Binomial Distribution

A binomial random variable $X$ counts the number of successes in $n$ independent Bernoulli trials with success probability $p$, $0 \leq p \leq 1$

$$P_p(X \leq k) = \sum_{i=0}^{k} \binom{n}{i} p^i (1 - p)^{n-i} \quad \text{and} \quad P_p(X \geq k) = 1 - P_p(X \leq k - 1).$$

It is intuitive that $P_p(X \leq k)$ is strictly decreasing in $p$ for $k = 0, 1, \ldots, n - 1$ and by complement $P_p(X \geq k)$ is strictly increasing in $p$ for $k = 1, 2, \ldots, n$.

$$\frac{\partial P_p(X \geq k)}{\partial p} = \sum_{i=k}^{n} \binom{n}{i} ip^{i-1} (1 - p)^{n-i} - \sum_{i=k}^{n-1} \binom{n}{i} (n - i) p^i (1 - p)^{n-i-1}$$

$$= n \sum_{i=k}^{n} \binom{n-1}{i-1} p^{i-1} (1 - p)^{n-i} - n \sum_{i=k}^{n-1} \binom{n-1}{i} p^i (1 - p)^{n-i-1}$$

$$= k \binom{n}{k} p^{k-1} (1 - p)^{n-k} > 0.$$
Useful Identities

For $k > 0 \implies$ binomial tail summations $\sim$ Beta cdf or incomplete Beta function,

$$ P_p(X \geq k) = \sum_{i=k}^{n} \binom{n}{i} p^i (1-p)^{n-i} = I_p(k, n-k+1) \quad (1) $$

$$ P_p(X \leq k) = 1 - P_p(X \geq k+1) = 1 - I_p(k+1, n-k) \quad (2) $$

where

$$ I_y(a,b) = \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \int_0^y t^{a-1} (1-t)^{b-1} \, dt = P(Y \leq y) $$

denotes the cdf of a beta random variable $Y$ with parameters $a > 0$ and $b > 0$.

$$ \frac{\partial}{\partial p} I_p(k, n-k+1) = \frac{\partial}{\partial p} \frac{\Gamma(n+1)}{\Gamma(k)\Gamma(n-k+1)} \int_0^p t^{k-1} (1-t)^{n-k} \, dt $$

$$ = \frac{\partial}{\partial p} k\binom{n}{k} \int_0^p t^{k-1} (1-t)^{n-k} \, dt = k\binom{n}{k} p^{k-1} (1-p)^{n-k} $$

(since $\Gamma(n+1) = n!$ for integer $n$) same as $\partial P_p(X \geq k) / \partial p$

$$ \implies (1) \text{ since } I_p(k, n-k+1) - P_p(X \geq k) = 0 - 0 = 0 \text{ for } p = 0.$$
General Binomial Monotonicity Property

If the function $\psi(x)$, defined for $x = 0, 1, \ldots, n$, is monotone increasing (decreasing) and not constant, then the expectation $E_p(\psi(X))$ is strictly monotone increasing (decreasing) in $p$.

$$\frac{\partial E_p(\psi(X))}{\partial p} = \frac{\partial}{\partial p} \sum_{x=0}^{n} \binom{n}{x} p^x (1 - p)^{n-x} \psi(x)$$

$$= \sum_{x=1}^{n} \binom{n}{x} x p^{x-1} (1 - p)^{n-x} \psi(x) - \sum_{x=0}^{n-1} \binom{n}{x} (n-x) p^x (1 - p)^{n-x-1} \psi(x)$$

$$= n \sum_{x=1}^{n} \binom{n-1}{x-1} p^{x-1} (1 - p)^{n-x} \psi(x) - n \sum_{x=0}^{n-1} \binom{n-1}{x} p^x (1 - p)^{n-x-1} \psi(x)$$

$$= n \sum_{y=0}^{n-1} \binom{n-1}{y} p^y (1 - p)^{n-1-y} \psi(y+1) - n \sum_{x=0}^{n-1} \binom{n-1}{x} p^x (1 - p)^{n-x-1} \psi(x)$$

$$= n \sum_{y=0}^{n-1} \binom{n-1}{y} p^y (1 - p)^{n-1-y} [\psi(y+1) - \psi(y)] > 0 \quad \text{q.e.d.}$$
Testing Hypotheses Concerning \( p \)

Testing the hypothesis \( H(p_0) : p = p_0 \) against the alternative \( A(p_0) : p < p_0 \) we would view small values of \( X \) as evidence against the hypothesis \( H(p_0) \).

Thus we reject \( H(p_0) \) at target significance level \( \alpha \) when \( X \leq k(p_0, \alpha) \), where the critical value \( k(p_0, \alpha) \) is chosen as the largest integer \( k \) for which

\[
P_{p_0}(X \leq k) \leq \alpha \quad \implies \quad P_{p_0}(X \leq k(p_0, \alpha) + 1) > \alpha.
\]

This controls the probability of type I error (rejecting \( H(p_0) \) when true) at \( \leq \alpha \).

For an observed value \( x \) of \( X \) we reject \( H(p_0) \) at level \( \alpha \) whenever the \( p \)-value \( p(x, p_0) = P_{p_0}(X \leq x) \leq \alpha \). That happens exactly when \( x \leq k(p_0, \alpha) \).

This view avoids the search for \( k(p_0, \alpha) \) and tells us how strongly we reject \( H(p_0) \), i.e., for how small an \( \alpha \) we would have rejected \( H(p_0) \) for that \( x \).

\( p(x, p_0) \) is also called the observed significance level.
Binomial Distribution: Density

\[ P_{p_0}(X=x) \]

\[ x \]

\[ 0 \quad 10 \quad 20 \quad 30 \quad 40 \]

\[ 0.00 \quad 0.04 \quad 0.08 \quad 0.12 \]
Binomial Distribution: CDF

\[ p(x, p_0) = P_{p_0}(X \leq x) \]

\[ k(p_0, \alpha) = 6 \]

\[ n = 40, \quad p_0 = 0.3 \]

\[ \alpha = 0.05 \]

accept \( H(p_0) \) since \( p(x, p_0) > 0.05 \)

reject \( H(p_0) \) since \( p(x, p_0) \leq 0.05 \)
Duality of Testing Hypotheses and Confidence Sets for $p$

We accept $H(p_0)$ whenever the $p$-value $p(x, p_0) = P_{p_0}(X \leq x) > \alpha$.

For an observed value $x$ of $X$ define the confidence set $C(x)$ for $p$ as all those values $p_0$ for which we would accept $H(p_0)$, i.e.,

$$C(x) = \{ p_0 : p(x, p_0) = P_{p_0}(X \leq x) > \alpha \}.$$

$P_{p_0}(X \leq x)$ is continuous and strictly decreasing in $p_0$ for $x < n$. It follows that $C(x) = [0, \hat{p}_U(1 - \alpha, x, n))$, where $\hat{p}_U(1 - \alpha, x, n)$ is the unique value $p$ that solves

$$P_p(X \leq x) = \sum_{i=0}^{x} \binom{n}{i} p^i (1 - p)^{n-i} = 1 - I_p(x + 1, n - x) = \alpha$$

or

$$I_p(x + 1, n - x) = 1 - \alpha = \gamma$$

i.e., $\hat{p}_U(1 - \alpha, x, n) = \hat{p}_U(\gamma, x, n)$ is the $\gamma$-quantile of the beta distribution with parameters $x + 1$ and $n - x$ or using R/S-Plus or Excel, respectively:

$$\hat{p}_U(\gamma, x, n) = q\text{beta}(\gamma, x + 1, n - x) = \text{BETAINV}(\gamma, x + 1, n - x) \quad \text{for } x < n$$

These bounds are also referred to as Clopper-Pearson bounds.
### Special Case \( x = n \)

When \( x = n \) we cannot use `qbeta` or `BETAINV`, since \( n - x = 0 \).

From the direct definition it follows that \( C(n) = [0, 1] \), closed on the right.

since \( P_{p_0}(X \leq n) = 1 > \alpha \quad \forall p_0 \).

In concordance with that we define \( \hat{p}_U(\gamma, n, n) = 1 \) with the understanding that the confidence set should be closed on the right in that case.
Confidence Level of $C(X)$

We can view this collection of confidence sets \( \{C(x) : x = 0, 1, \ldots, n\} \) also as a random set $C(X)$.

It has the following coverage probability property for any $p_0$

\[
P_{p_0}(p_0 \in C(X)) = 1 - P_{p_0}(p_0 \notin C(X)) = 1 - P_{p_0}(\text{reject } H(p_0)) \geq 1 - \alpha = \gamma
\]

Note that in this coverage probability it is the set $C(X)$ that is random, not $p_0$!

This holds for any $p_0$, whether we know it or not. We drop the subscript $0$ and write

\[
P_p(p \in C(X)) = P_p(p < \hat{p}_U(\gamma, X, n)) \geq \gamma \quad \forall p
\]

$\hat{p}_U(\gamma, X, n)$ is called a \textit{100$\gamma$% upper confidence bound} for the unknown $p$.

Here $p < \hat{p}_U(\gamma, X, n)$ should be read as $p \leq \hat{p}_U(\gamma, X, n)$ when $X = n$. 
The confidence coefficient of the upper bound is defined as

\[
\bar{\gamma} = \inf_p \{P_p (p \in C(X))\} = \inf_p \{P_p (p < \hat{p}_U(\gamma, X, n))\}.
\]

The confidence coefficient is \(\bar{\gamma} = \gamma = 1 - \alpha\) since \(P_p (p \in C(X)) = \gamma\) for some \(p\),

or \(P_p (p \notin C(X)) = P_p (X \leq k(p, \alpha)) = 1 - \gamma = \alpha\) for some \(p\).

Proof: Recall that for \(x = 0, 1, \ldots, n - 1\) the value \(p = \hat{p}_U(\gamma, x, n)\) solved

\[P_p(X \leq x) = \alpha\]

Thus for \(p_i = \hat{p}_U(\gamma, i, n), i = 0, 1, \ldots, n - 1\), with \(k(p_i, \alpha) = i\) we have

\[P_{p_i}(X \leq k(p_i, \alpha)) = P_{p_i}(X \leq i) = \alpha,\quad (4)\]

i.e., the infimum above is indeed attained at \(p = p_0, p_1, \ldots, p_{n-1}\).
An Example and Some Observations

As a check example use the case $k = 12$ and $n = 1600$ with $\gamma = .95$, then one gets $\hat{p}_U(.95, 12, 1600) = \text{qbeta}(.95, 12 + 1, 1600 - 12) = .01212334$ as 95% upper confidence bound for $p$.

Using (3) it is a simple exercise to show that the sequence of upper bounds is strictly increasing in $x$, i.e.,

$$0 < \hat{p}_U(\gamma, 0, n) < \hat{p}_U(\gamma, 1, n) < \ldots < \hat{p}_U(\gamma, n - 1, n) < \hat{p}_U(\gamma, n, n) = 1.$$ 

$$\implies P_p(p < \hat{p}_U(\gamma, X, n)) = 1 \quad \forall p < \hat{p}_U(\gamma, 0, n).$$

Explicit expressions for $x = 0$ and $x = n - 1$

$$\hat{p}_U(\gamma, 0, n) = 1 - (1 - \gamma)^{1/n} \quad \text{and} \quad \hat{p}_U(\gamma, n - 1, n) = \gamma^{1/n}.$$ 

The first case is more useful than the second.
Estimates in Relation to Upper Confidence Bounds

\[ \gamma = 0.95, \quad n = 100 \]

\[ 0.02951 = \text{smallest possible upper bound} \]

\[ \hat{p}_u(x) \]

- **estimates**
- **upper bounds**
The Rule of Three

For $\gamma = .95$ and approximating $\log(1 - \gamma) = \log(.05) = -2.995732$ by $-3$

the upper bound for $x = 0$ becomes

$$\hat{p}_U(.95, 0, n) = 1 - (.05)^{1/n} = 1 - \exp\left[\frac{\log(.05)}{n}\right] \approx 1 - \exp(-3/n) \approx \frac{3}{n},$$

Here the last approximation is valid only for large $n$, say $n \geq 100$.

This is sometimes referred to as the Rule of Three (mnemonic simplicity!)

$\hat{p}_U(.95, 0, n) = 3/n$ is very useful for quick sample size planning,

based on the a priori conviction of seeing $x = 0$ successes in $n$ trials.
Side Comment on Common Practice when $x = 0$

Observing $X = 0$ successes in $n$ trials, especially when $n$ is large, we still are not inclined to estimate the success probability $p$ by $\hat{p}(0) = 0/n = 0$, since that is a very strong statement.

$p = 0 \implies$ we will never see a success in however many trials.

One common practice to get out of this dilemma is to “conservatively” pretend that the first success is just around the corner, i.e., happens on the next trial. Thus estimate $p$ by $\tilde{p} = 1/(n+1)$ which is small but not zero.

The use of $\tilde{p}$ as estimate of $p$ is somewhat conservative. How conservative?

Find $\gamma$ such that $\hat{p}_U(\gamma,0,n) = 1 - (1 - \gamma)^{1/n} = 1/(n+1)$

$\gamma = 1 - \left(\frac{n}{n+1}\right)^n = 1 - \left(1 - \frac{1}{n+1}\right)^n \approx 1 - \exp\left(-\frac{n}{n+1}\right) \approx 1 - \exp(-1) = .6321$.

Can view $\tilde{p} = 1/(n+1)$ as a 63.21% upper confidence bound for $p$. 
Closed or Open Intervals?

So far we have given the confidence sets in terms of the right open intervals $[0, \hat{p}_U(\gamma, x, n))$ with the property that

$$P_p(p < \hat{p}_U(\gamma, X, n)) \geq \gamma \quad \text{and} \quad \inf_p \{P_p(p < \hat{p}_U(\gamma, X, n))\} = \gamma,$$

where the value $\gamma$ is achieved at $p = \hat{p}_U(\gamma, x, n)$ for $x = 0, 1, \ldots, n - 1$.

The question arises quite naturally: why not take instead the right closed interval $[0, \hat{p}_U(\gamma, x, n)]$, again with property

$$P_p(p \leq \hat{p}_U(\gamma, X, n)) \geq \gamma \quad \text{and} \quad \inf_p \{P_p(p \leq \hat{p}_U(\gamma, X, n))\} = \gamma.$$

The difference is that the infimum is not achieved at any $p$.

Whether we use the closed interval or not, the definition of $\hat{p}_U(\gamma, x, n)$ stays the same. Any value $p_0$ equal to it or greater would lead to rejection of $H(p_0)$ when tested against $A(p_0) : p < p_0$. By closing the interval we add a single $p$ to it, namely $p = \hat{p}_U(\gamma, x, n)$. That $p$ is not an acceptable hypothesis $H(p)$ for this $x$. 
Continuity Properties of the Coverage Probability

Let \( p_i = \hat{p}(\gamma, i, n) \) for \( i = 0, 1, \ldots, n \). Recall \( 0 < p_0 < p_1 < \ldots < p_n = 1 \).

For \( p \in [p_{i-1}, p_i) \) the set \( A = \{ j : p < \hat{p}(\gamma, j, n) \} = [i, n] \) does not change.

\[ \Rightarrow \quad P_p(X \in A) = P_p(X \geq i) \quad \text{increases continuously in } p \text{ over } [p_{i-1}, p_i). \]

When \( p = p_i \) the set \( A \) loses the value \( j = i \) and \( P_p(p < \hat{p}(\gamma, X, n)) \) drops by \( P_{p_i}(X = i) \) to \( P_{p_i}(X \geq i + 1) = 1 - P_{p_i}(X \leq i) = 1 - \alpha = \gamma \) see (4), and so on.

For \( p \in (p_{i-1}, p_i] \) the set \( B = \{ j : p \leq \hat{p}(\gamma, j, n) \} = [i, n] \) does not change.

\[ \Rightarrow \quad P_p(X \in B) = P_p(X \geq i) \quad \text{increases continuously in } p \text{ over } (p_{i-1}, p_i]. \]

As \( p \searrow p_{i-1} \) we have \( P_p(X \geq i) \searrow P_{p_{i-1}}(X \geq i) = 1 - P_{p_{i-1}}(X \leq i - 1) = 1 - \alpha = \gamma \) see (4), but at \( p = p_{i-1} \) we have a jump since

\[ P_{p_{i-1}}(p_{i-1} \leq \hat{p}(\gamma, X, n)) = P_{p_{i-1}}(X \geq i - 1) > P_{p_{i-1}}(X \geq i), \]
i.e., \( \gamma \) is never attained.
Coverage Probability of Upper Confidence Bounds

nominal confidence level = 0.95
sample size n = 10
Confidence Lower Bounds on $p$

When testing $H(p_0) : p = p_0$ against the alternative $A(p_0) : p > p_0$ large values of $X$ can be viewed as evidence against $H(p_0)$.

Again carry out the test in terms of the observed $p$-value $p(x, p_0) = P_{p_0}(X \geq x)$ by rejecting $H(p_0)$ at level $\alpha$ whenever $p(x, p_0) \leq \alpha$ and accepting $H(p_0)$ otherwise.

From the duality between testing and confidence sets we get as confidence set

$$C(x) = \{ p_0 : p(x, p_0) = P_{p_0}(X \geq x) > \alpha \}.$$

Since $P_{p_0}(X \geq x)$ is strictly increasing and continuous in $p_0$ we see that for $x = 1, 2, \ldots, n$ this confidence set $C(x)$ coincides with the interval $(\hat{p}_L(\gamma, x, n), 1]$, where $\hat{p}_L(\gamma, x, n)$ is that value of $p$ that solves

$$P_p(X \geq x) = \sum_{i=x}^{n} \binom{n}{i} p^i (1 - p)^{n-i} = \alpha = 1 - \gamma.$$  

(5)
Confidence Lower Bounds on $p$ (cont.)

Invoking the identity (1) this value $p$ can be obtained by solving

$$I_p(x, n-x+1) = \alpha = 1 - \gamma$$

for $p$, i.e., it is the $\alpha$-quantile of a Beta distribution with parameters $x$ and $n-x+1$.

Using R/S-Plus or Excel we get it for $x > 0$ as

$$\hat{p}_L(\gamma, x, n) = \text{qbeta}(1-\gamma, x, n-x+1) = \text{BETAINV}(1-\gamma, x, n-x+1)$$

For $x = 0$ we have $P_{p_0}(X \geq 0) = 1 > \alpha$ and we cannot use (5), but the original definition of $C(x)$ leads to $C(0) = [0, 1]$.

We define $\hat{p}_L(\gamma, 0, n) = 0$ in that case, with the understanding that the left-open interval $(\hat{p}_L(\gamma, x, n), 1]$ becomes closed when $x = 0$. 
An Example and Some Observations

As a check example take \( x = 4 \) and \( n = 500 \) with \( \gamma = .95 \), then one gets
\[
\hat{p}_L(.95, 4, 500) = qbeta(.05, 4, 497) = .002737
\]
as 95\% lower bound for \( p \).

Using (5) it is a simple exercise to show that the sequence of lower bounds is strictly increasing in \( x \), i.e.,
\[
0 = \hat{p}_L(\gamma, 0, n) < \hat{p}_L(\gamma, 1, n) < \ldots < \hat{p}_L(\gamma, n-1, n) < \hat{p}_L(\gamma, n, n) < 1 .
\]
\[\implies P_p(\hat{p}_L(\gamma, X, n) < p) = 1 \quad \text{for} \quad p > \hat{p}_L(\gamma, n, n).\]

As in the case of the upper bound one may prefer to use the closed confidence set
\[
[\hat{p}_L(\gamma, x, n), 1],
\]
with the corresponding commentary.

In particular, the lower endpoint \( p_0 = \hat{p}_L(\gamma, x, n) \) does not represent an acceptable hypothesis value, while all other interval points are acceptable values.
Special Cases

For $x = 1$ and $x = n$ the lower bounds defined by (5) can be expressed explicitly as

$$\hat{p}_L(\gamma, 1, n) = 1 - \gamma^{1/n} \quad \text{and} \quad \hat{p}_L(\gamma, n, n) = (1 - \gamma)^{1/n}$$

For obvious reasons the explicit lower bound in the case of $x = n$ is of more practical interest than the lower bound for $x = 1$.

For $\gamma = .95$ and $x = n$ the lower bound becomes

$$\hat{p}_L(.95, n, n) = (1 - .95)^{1/n} \approx \exp(-3/n) \approx 1 - \frac{3}{n},$$

a dual instance of the Rule of Three. The last approximation is valid for large $n$.

This duality should not surprise since switching the role of successes and failures with concomitant switch of $p$ and $1 - p$ turns upper bounds for $p$ into lower bounds for $p$ and vice versa.

When observing $X = n$ successes in $n$ trials, especially when $n$ is large, we still are not inclined to estimate $p$ by $\hat{p} = n/n = 1$, because of the consequences of such a strong statement.
\[ \hat{p}_L(1 - \alpha/2, X, n) < \hat{p}_U(1 - \alpha/2, X, n) \]

for \( 0 < \alpha < 1 \) \( \quad P_p(\hat{p}_L(1 - \alpha/2, X, n) < \hat{p}_U(1 - \alpha/2, X, n)) = 1 \quad \) for any \( p \).

Suppose \( \hat{p}_U(1 - \alpha/2, x, n) \leq \hat{p}_L(1 - \alpha/2, x, n) \) for some \( x \)

\[ \Rightarrow \hat{p}_U(1 - \alpha/2, x, n) \leq p_0 \leq \hat{p}_L(1 - \alpha/2, x, n) \] for some \( p_0 \) and some \( x \).

With that \( x \) the hypothesis \( H(p_0) : p = p_0 \) would be rejected when testing against \( A(p_0) : p < p_0 \) or \( \tilde{A}(p_0) : p > p_0 \), i.e.,

\[ P_{p_0}(X \leq x) \leq \alpha/2 \quad \text{and} \quad P_{p_0}(X \geq x) \leq \alpha/2 \]

and by adding those two inequalities we get

\[ 1 + P_{p_0}(X = x) \leq \alpha < 1 , \quad \text{i.e., a contradiction.} \]
Confidence Intervals for $p$

Lower and upper confidence bounds, each with respective confidence coefficient $1 - \alpha/2$, can be used simultaneously as a $100(1 - \alpha)\%$ confidence interval

$$(\hat{p}_L(1 - \alpha/2, X, n), \hat{p}_U(1 - \alpha/2, X, n)).$$

$\hat{p}_L(1 - \alpha/2, x, n) < \hat{p}_U(1 - \alpha/2, x, n)$ for any $p$ and any $x = 0, 1, \ldots, n$

$$P_p(\hat{p}_L(1 - \alpha/2, X, n) < p < \hat{p}_U(1 - \alpha/2, X, n))$$
$$= 1 - P_p(p \leq \hat{p}_L(1 - \alpha/2, X, n) \cup \hat{p}_U(1 - \alpha/2, X, n) \leq p)$$
$$= 1 - [P_p(p \leq \hat{p}_L(1 - \alpha/2, X, n)) + P_p(\hat{p}_U(1 - \alpha/2, X, n) \leq p)]$$
$$\geq 1 - [\alpha/2 + \alpha/2] = 1 - \alpha.$$
Confidence Coefficient of Confidence Intervals for $p$

\[\bar{\gamma} = \inf_P P_p(\hat{p}_L(1 - \alpha/2, X, n) \leq p \leq \hat{p}_U(1 - \alpha/2, X, n))\]

\[= 1 - \sup_P P_p(p < \hat{p}_L(1 - \alpha/2, X, n) \cup \hat{p}_U(1 - \alpha/2, X, n) < p)\]

\[= 1 - \sup_P \left\{P_p(p < \hat{p}_L(1 - \alpha/2, X, n)) + P_p(\hat{p}_U(1 - \alpha/2, X, n) < p)\right\}\]

\[\geq 1 - \left\{\sup_P P_p(p < \hat{p}_L(1 - \alpha/2, X, n)) + \sup_P P_p(\hat{p}_U(1 - \alpha/2, X, n) < p)\right\}\]

\[= 1 - \{\alpha/2 + \alpha/2\} = 1 - \alpha.\]

The inequality $\geq$ typically takes the strict form $>$

since the suprema are usually not attained or approached at the same $p$. 

24
Coverage Probabilities

The coverage plots shown here were produced in R. In the case of the lower bound coverage probability calculate for fine grid of $p$ values

$$P(\hat{p}_L(\gamma, X, n) \leq p) = (1 - p)^n + \sum_{x=1}^{n} I\{qbeta(1-\gamma,x,n-x+1) \leq p\} \binom{n}{x} p^x (1 - p)^{n-x},$$

where $I_A = 1$ whenever $A$ is true and $I_A = 0$ otherwise. For the upper bound one computes the coverage probabilities via

$$P(\hat{p}_U(\gamma, X, n) \geq p) = \sum_{x=0}^{n-1} I\{qbeta(\gamma,x+1,n-x) \geq p\} \binom{n}{x} p^x (1 - p)^{n-x} + p^n,$$

while for the confidence interval one calculates the coverage probability as

$$P(\hat{p}_L((1+\gamma)/2, X, n) \leq p \cap \hat{p}_U((1+\gamma)/2, X, n) \geq p)$$

$$= \sum_{x=1}^{n-1} I\{qbeta((1-\gamma)/2,x,n-x+1) \leq p \cap qbeta((1+\gamma)/2,x+1,n-x) \geq p\} \binom{n}{x} p^x (1 - p)^{n-x}$$

$$+(1 - p)^n I\{qbeta((1+\gamma)/2,1,n) \geq p\} + p^n I\{qbeta((1-\gamma)/2,1,1) \leq p\}.$$

Coverage Probability of Upper Confidence Bounds

nominal confidence level = 0.95
sample size n = 100
Coverage Probability of Lower Confidence Bounds

nominal confidence level = 0.95
sample size n = 100
Coverage Probability of Confidence Intervals

nominal confidence level = 0.95
sample size $n = 100$
Coverage Probability of Confidence Intervals \( (n = 11) \)

Probability of Coverage for \( [\hat{p}^L, \hat{p}^U] \) nominal confidence level = 0.95
sample size \( n = 11 \)
Confidence Intervals for $p \approx 0$ or $p \approx 1$

As the previous plots showed, for intervals the coverage probabilities stay above $1 - \alpha/2 = 1 - (1 - \gamma)/2 = (1 + \gamma)/2$ for $p$ near 0 or 1.

This is a consequence of coverage probability 1 for upper bounds (lower bounds) when $p$ is near 0 (near 1):

$$P_p(\hat{p}_L(1 - \alpha/2, X, n) \leq p \leq \hat{p}_U(1 - \alpha/2, X, n)) = 1 - P_p(\hat{p}_L(1 - \alpha/2, X, n) > p) - P_p(\hat{p}_U(1 - \alpha/2, X, n) < p)$$

$$= 1 - P_p(\hat{p}_L(1 - \alpha/2, X, n) > p) \geq 1 - \alpha/2 \quad \text{for } p < \hat{p}_U(1 - \alpha/2, 0, n)$$

$$= 1 - P_p(\hat{p}_U(1 - \alpha/2, X, n) < p) \geq 1 - \alpha/2 \quad \text{for } p > \hat{p}_L(1 - \alpha/2, n, n)$$
Confidence Bounds or Intervals?

For $p \approx 0$ it makes little sense to use lower bounds or intervals, wasting half the miss probability where it does not matter.

Most often the lower bound would be 0 anyway, a useless piece of information.

One should then allocate all of the miss probability $\alpha$ to the upper bound, i.e., use

$$\hat{p}_U(1 - \alpha, X, n)$$

rather than

$$\hat{p}_U(1 - \alpha/2, X, n)$$

which is higher.

If $X = 0$ we can ask how large $m$ should be so that

$$\hat{p}_U(1 - \alpha/2, 0, m) = 1 - (\alpha/2)^{1/m} = \hat{p}_U(1 - \alpha, 0, n) = 1 - (\alpha)^{1/n}$$

$$m = n \times \frac{\log(\alpha) - \log(2)}{\log(\alpha)}$$

For $\alpha = .05$ we need $m = 1.2314 \times n$.

Corresponding comments apply for $p \approx 1$ and lower bounds.
Simulated Upper Bounds

To get a better understanding of the nature of confidence bounds we simulated 1000 instances of $X$ from a binomial distribution $\text{Bin}(n, p)$ for $n = 100$ and several different values of $p$.

The next slides show the resulting 95% upper confidence bounds in relation to the respective true values of $p$.

The $n + 1$ possible upper bounds are solely determined by $\gamma$ and the value $n$. Recall $q_{\text{beta}}(\gamma, x + 1, n - x)$ for $x = 0, 1, \ldots, n - 1$ and $\hat{p}_U(\gamma, n, n) = 1$.

As the true $p$ changes the distribution of $X$ changes.

One can clearly see how the zigzag behavior of the coverage probabilities arises.
Simulated 95% Upper Bounds for $p = 0.029$

- Sample size $n = 100$
- 0% of upper bounds $\hat{p}_U(x) \leq p = 0.029$
- Smallest possible upper bound = 0.02951
Simulated 95% Upper Bounds for $p = .030$

- Sample size $n = 100$
- 3.8% of upper bounds $\hat{\rho}_U(x) \leq p = 0.03$
- Smallest possible upper bound $= 0.02951$
Simulated 95% Upper Bounds for $p = .040$

- Sample size $n = 100$
- 1.7% of upper bounds $\hat{p}_u(x) \leq p = 0.04$
- Smallest possible upper bound $= 0.02951$
Simulated 95% Upper Bounds for $p = .043$

- Sample size $n = 100$
- 0.9% of upper bounds $\hat{p}_U(x) \leq p = 0.043$
- Smallest possible upper bound = 0.02951
Classical or Elementary Upper Bounds

In elementary statistics classes the following upper bound is usually presented

\[ \hat{p} + z_\gamma \sqrt{\frac{\hat{p}(1 - \hat{p})}{n}} \]  

with \( \hat{p} = \frac{x}{n} \) and \( z_\gamma = \gamma \)-quantile of \( Z \sim \mathcal{N}(0, 1) \).

It is based on the approximation

\[ \frac{\hat{p} - p}{\sqrt{\frac{\hat{p}(1 - \hat{p})}{n}}} \sim \mathcal{N}(0, 1) \quad \text{for large } n \quad \text{(poor for } p \text{ near 0 or 1).} \]

\[
P \left( p \leq \hat{p} + z_\gamma \sqrt{\frac{\hat{p}(1 - \hat{p})}{n}} \right) = P \left( -z_\gamma \leq \frac{\hat{p} - p}{\sqrt{\frac{\hat{p}(1 - \hat{p})}{n}}} \right) \approx P \left( -z_\gamma \leq Z \right) = P(Z \leq z_\gamma) = \gamma
\]

Confidence coefficient \( \gamma = 0 \),

since for very small \( p \) the upper bound becomes 0 with probability approaching 1.
Coverage Probability of Elementary 95% Upper Bounds

nominal confidence level = 0.95
sample size n = 100
Score Test Upper Bounds

Uses the same testing/confidence bounds duality as did Clopper-Pearson.

Here use a normal approximation to calculate the $p$-value $p(x, p_0) = P_{p_0}(X \leq x)$

Use $X \sim \mathcal{N}(np_0, np_0(1 - p_0))$ to find all acceptable $p_0$ with $P_{p_0}(X \leq x) > \alpha$, i.e., solve for $p_0$

$$\alpha = P_{p_0}(X \leq x) = P_{p_0} \left( \frac{X - np_0}{\sqrt{np_0(1 - p_0)}} \leq \frac{x - np_0}{\sqrt{np_0(1 - p_0)}} \right)$$

$$\approx P \left( Z \leq \frac{x - np_0}{\sqrt{np_0(1 - p_0)}} \right) \implies \frac{x - np_0}{\sqrt{np_0(1 - p_0)}} = z\alpha = -z_{1 - \alpha} = -z_\gamma$$

$$\implies \hat{p}_U(\gamma, x, n) = \frac{z^2 / (2n) + \hat{p}}{1 + z^2 / n} + \frac{z}{1 + z^2 / n} \sqrt{\frac{z^2}{4n^2} + \frac{\hat{p}(1 - \hat{p})}{n}}, \text{ with } z = z_\gamma$$

after some algebraic gyrations. Not very appealing or mnemonic.
Coverage Probability of Score Test 95% Upper Bounds

nominal confidence level $= 0.95$

sample size $n = 100$
Commentary on Score Test Upper Bounds

Agresti and Coull (1998) claim that score test confidence intervals (combining lower and upper bounds) show better average coverage behavior.

No continuity correction, using \( (x \pm .5)/n \) in the upper/lower bounds respectively.

We chose to examine this from the upper bound perspective. The claim seems OK, but for \( p \approx 1 \) the coverage deteriorates. That is of little interest. However, it averages out against the coverage probability of 1 near \( p = 0 \).

Average (like minimum) coverage probability is just another metric.

We could adjust the Clopper-Pearson bounds (lowering their minimum coverage) to have same average coverage behavior.

Trying to raise the score test bounds to have their minimum coverage equal that of the Clopper-Pearson bounds would be more problematic.

Both types of bounds show roughly the same type of zigzag swings.
Coverage Probability of Score Test 95% Upper Bounds with Continuity Correction

nominal confidence level = 0.95
sample size n = 100
Coverage Probability of Score Test 95% Confidence Intervals

nominal confidence level = 0.95
sample size n = 100
Airplanes are inspected for corrosion at a 10 year inspection interval.

All $n$ inspected aircraft made it through corrosion inspection without any findings.

Customer wants 95% lower confidence bounds on the probability of an airplane passing its corrosion inspection without any findings.

The customer did not tell me $n$, only that 2.5% of the fleet had been inspected. How do we deal with this, not knowing the fleet size?

View each airplane’s corrosion experience over a 10 year exposure window as a Bernoulli trial with probability $p$ of surviving 10 years without corrosion.

$X = \text{number of aircraft without any corrosion found at their respective inspections}$

is a binomial random variable with parameters $n$ and success probability $p$.

$X = n \implies \hat{p}_L(.95, n, n) = (1 - .95)^{1/n}$.

Plot $\hat{p}_L(.95, n, n)$ against $n$ and the customer can take it from there.
Lower 95% Confidence Bounds as Function of $n$

95% lower confidence bound on $p = P$(no corrosion in 10 years)

number $n$ of planes inspected, all without corrosion findings
Some Commentary

Each such inspection involves extensive stripping of aircraft interior.

An airline may have asked about the necessity of this onerous and costly task after finding no corrosion in $n$ inspection.

Maybe it is felt that the inspection interval should be increased so that cost is spread out over more service life.

On the other hand, if corrosion is detected early it is a lot easier and cheaper to fix than when it has progressed beyond extensive or impossible repair.

If this airline has 200 aircraft of which 2.5% (or $n = 5$) had their 10 year check, all corrosion free, then the 95% lower bound on $p$ is about .55.

This is not very reassuring.
Space Shuttle Stud Hang-Ups

- Blast Container
- Holddown Stud
- SRB Aft Skirt
- Frangible Nut
- Aft Skirt Shoe
- MLP Support Post

Ejection into post
The Issues and Facts

The studs have 3.5″ diameter. If they do not drop through cleanly they hang up.

This can even be felt in the shuttle cabin.

It impacts some performance parameters (indicators): how severely?

In an extreme case the studs just snap under the tremendous takeoff force.

In 114 liftoffs there were 21 with one hang-up and 2 with two hang-ups.

No liftoff with more than 2 hang-ups.

There are 4 studs per Solid Rocket Booster (SRB), 8 total.

http://www.eng.uab.edu/ME/ETLab/HSC04/abstracts/HSC147.pdf
and http://www.nasa.gov/offices/nesc/home/Feature_1.html
Modeling and a Check

If we treat each liftoff as 8 Bernoulli trials (one for each stud) we have experienced $114 \times 8 = 912$ trials, with $21 \times 1 + 2 \times 2 = 25$ “successes.” We get $\hat{p} = 25/912 = .02741$ as estimate of our success probability.

If indeed the 8 studs per liftoff act as independent Bernoulli trials we would estimate the probability of seeing $i$ hang-ups in a liftoff as

$$\hat{p}_i = \binom{8}{i} \hat{p}^i (1 - \hat{p})^{8-i}.$$

From this one gets $\hat{p}_0 = 0.8006$, $\hat{p}_1 = 0.1805$, $\hat{p}_2 = 0.0178$, and $\hat{p}_{3+} = 0.0010$.

Based on this one would have expected $E_i = \hat{p}_i \times 114$ liftoffs with $i$ stud hang-ups. $\implies \ E_0 = 91.27, \ E_1 = 20.58, \ E_2 = 2.03 \text{ and } E_{3+} = 0.12$

These compare reasonably well with the observed counts of $O_0 = 91, \ O_1 = 21, \ O_2 = 2$, and $O_{3+} = 0$.

Thus we do not have any indications that contradict the above assumption of independence and constant probability $p$ of a stud hang-up.
The Clopper-Pearson 95% upper confidence bound for $p$ is

$$\hat{p}_u(.95, 25, 912) = q_{\text{beta}}(.95, 25 + 1, 912 - 25) = 0.03807645 .$$

If $X$ denotes the number of stud hang-ups during a single liftoff, we may be interested in an upper bound on the probability of seeing more than 3 hang-ups.

Since $P_p(X \geq 4) = f_4(p)$ is monotone increasing in $p$ we can use

$$f_4(\hat{p}_u(.95, 25, 912)) = 1 - \text{pbinom}(3, 8, 0.03807645) = 0.00013$$

as 95% upper bound for this risk $f_4(p)$, since

$$P_p(f_4(p) \leq f_4(\hat{p}_u(.95, X, 912))) = P_p(p \leq \hat{p}_u(.95, X, 912)) \geq .95$$

Because of the small risk upper bound of 0.00013 it was decided to focus further concerns to $X \leq 3$. 
Simulations of Indicators

NASA has intricate programs that can simulate liftoffs with many randomly varying environmental inputs, material properties, etc. It takes considerable time to run these simulations.

Before each mission (with different payloads) liftoff simulations are carried out: 800 each, under 0 hang-ups, 1 hang-up, 2 hang-ups, and 3 hang-ups.

For each simulation many indicator variables (stresses, deviation angles, etc.) are monitored. Each such indicator $Y$ has a safe range or a safe threshold, say $y_0$.

The task was to determine the $3\sigma$ risk for each of those indicators.

In the engineering world $3\sigma$ refers to a normal distribution and implies a risk of $0.00135$ of a normal random variable deviating by more than $3\sigma$ above (or below) its mean. The 2-sided risk is $0.0027$. 
Law of Total Probability

Recall the following law of total probability which facilitates probability calculations for events, that are complex initially but become easier to manage when split into several mutually exclusive cases.

Suppose \( B_1 \cup \ldots \cup B_k = \Omega \) (full probability space) with \( B_i \cap B_j = \emptyset \) for \( i \neq j \)

\[
P(A) = P(A \cap \{B_1 \cup \ldots \cup B_k\}) = P(\{A \cap B_1\} \cup \ldots \cup \{A \cap B_k\})
\]
\[
= P(A \cap B_1) + \ldots + P(A \cap B_k) \quad \text{since} \quad \{A \cap B_i\} \cap \{A \cap B_j\} = \emptyset \quad \text{for} \quad i \neq j
\]
\[
= P(A|B_1)P(B_1) + \ldots + P(A|B_k)P(B_k)
\]

since \( P(A|B_i) = P(A \cap B_i)/P(B_i) \) by definition.
It is desired to get an upper confidence bound for \( \bar{F}_p(y_0) = P_p(Y > y_0) \).

By conditioning on \( X = k \) we have the following expression for \( \bar{F}_p(y_0) \)

\[
\bar{F}_p(y_0) = P(Y > y_0 | X = 0)P_p(X = 0) + P(Y > y_0 | X = 1)P_p(X = 1) \\
+ P(Y > y_0 | X = 2)P_p(X = 2) + P(Y > y_0 | X = 3)P_p(X = 3) \\
+ P(Y > y_0 | X \geq 4)P_p(X \geq 4)
\]

\[
= \sum_{x=0}^{3} P(Y > y_0 | X = x)P_p(X = x) + P(Y > y_0 | X \geq 4)P_p(X \geq 4)
\]

\[
\leq \sum_{x=0}^{3} P(Y > y_0 | X = x)P_p(X = x) + P_p(X \geq 4) = \bar{G}_p(y_0).
\]

For many (but not for all) of the response variables one can plausibly assume that \( P(Y > y_0 | X = x) \) increases with \( x \).
Using the Binomial Monotonicity Property for $E_p(\psi(X))$

Using $\psi(x) = P(Y > y_0|X = x)$ for $x = 0, 1, 2, 3$ and $\psi(x) = 1$ for $x > 3$ we can write

$$\tilde{G}_p(y_0) = E_p(\psi(X))$$

Based on the general binomial monotonicity property get an upper confidence bound for $\tilde{G}_p(y_0)$ (and thus conservatively also for $\tilde{F}_p(y_0)$) by replacing $p$ by the appropriate upper bound $\hat{p}_U(.95, 25, 912)$ in the expression for $\tilde{G}_p(y_0)$.

To do so would require knowledge of the exceedance probabilities $P(Y > y_0|X = x)$ for $x = 0, 1, 2, 3$. These would come from the four sets of simulations that were run. Of course such simulations can only estimate $P(Y > y_0|X = x)$ with their accompanying uncertainties, but that is an issue we won’t address here.
Simulated CDF of Indicator Variable

\[ F(x) = \text{proportion of sample } X_i \leq x \]

- 0 hang-ups
- 1 hang-up
- 2 hang-ups
- 3 hang-ups
Magnified CDF of Indicator Variable

$F(x) = \text{proportion of sample } X_i \leq x$

- 0 hang-ups
- 1 hang-up
- 2 hang-ups
- 3 hang-ups

Proportion above 55:
- 0
- 0.00875
- 0.03375
- 0.08375
Bounding $\bar{G}_p(55) \geq P(Y > 55)$

Based on the numbers 0, .00875, .03375, and .08375 from the previous slide and the upper bound $\hat{p}_U(.95, 25, 912) = .03807645 = \hat{p}_U$ for $p$ we calculate the following 95% upper confidence bound for $\bar{G}_p(55) \geq P(Y > 55)$

$$0 \times \binom{8}{0} \hat{p}_U^0 (1 - \hat{p}_U)^8 + .00875 \times \binom{8}{1} \hat{p}_U (1 - \hat{p}_U)^7 + .03375 \times \binom{8}{2} \hat{p}_U^2 (1 - \hat{p}_U)^6$$

$$+.08375 \times \binom{8}{3} \hat{p}_U^3 (1 - \hat{p}_U)^5 + \sum_{j=4}^{8} \binom{8}{j} \hat{p}_U^j (1 - \hat{p}_U)^{8-j} = 0.003459802$$

This is larger than the .00135 risk associated with the $3\sigma$ requirement.

Even the estimate of $\bar{G}_p(55)$ (using $\hat{p} = 25/912$ instead of $\hat{p}_U$) only yields 0.002300867.
Some Comments

Thus it is not the 95% confidence bound that is at issue here.

However, while the data are somewhat real (transformed from real data) the threshold is entirely fictitious.

It was chosen to point out what might happen in such (rare) situations.

When the risk upper bound does not fall below the allowed 3σ value of .00135 there usually is an action item to revisit the requirements for the chosen threshold.

Often these are chosen conservatively and an engineering review of the involved stresses or angular deviations may justify a relaxation of these thresholds.

These kinds of analyses can whittle down the number of cases where serious engineering review is warranted.
Perspectives on Risk Levels

The risks in the Space Shuttle program are of a different order of magnitude than those tolerated in commercial aviation.

In the latter arena one often is confronted by the requirement of demonstrating a risk of $10^{-9}$ or less, i.e., expect at most one bad event in $10^9$ departures.

This appears to be based on the assumption: \# of flight critical systems $\leq 100$.

If each such system is designed to the $10^{-9}$ requirement then the chance of at least one of these systems failing is at most $100 \times 10^{-9} = 10^{-7}$.

This is still well below the current rate of hull losses and most of these are not due to any aircraft design deficiencies. See page 17 of

17% of hull losses during 1996-2005 pointed to the Airplane as the primary cause.
Establishing a $10^{-9}$ risk directly from system exposure data is difficult if not impossible, and certainly impracticable during the design phase.

The low exponent ($-9$) of such risks is built up by multiplying verifiable risks of higher order, e.g., $10^{-4} \times 10^{-5} = 10^{-9}$

Such multiplication is based on statistical independence and redundancy in the design, like having at least two engines on a plane, or doing engine maintenance at different times or by different mechanics.

This difference in risk levels in the Space Program as compared to commercial aviation is based on many factors.

Major drivers among these are the frequency with which the risk is taken and the consequences (loss of lives and financial losses) of a catastrophic event.
The Negative Binomial Distribution

A negative binomial random variable $N$ counts the number of required independent trials, with success probability $p$ ($0 \leq p \leq 1$) in each trial, in order to obtain a predetermined number $k$ of successes.

\[
P_p(N = n) = \binom{n-1}{k-1} p^k (1-p)^{n-k}, \ n = k, k+1, \ldots
\]

\[
= P(k - 1 \text{ successes in the first } n - 1 \text{ trials } \cap \text{ a success in the } n^{\text{th}} \text{ trial}).
\]

From a different angle we have

\[
P_p(N \geq n) = \sum_{i=0}^{k-1} \binom{n-1}{i} p^i (1-p)^{n-1-i}
\]

\[
= P( \text{ at most } k - 1 \text{ successes in the first } n - 1 \text{ trials}).
\]
Monotonicity of the Negative Binomial CDF

It should get easier to satisfy the quota of $k$ successes earlier as $p$ increases.

Thus we expect $P_p(N \geq n)$ to decrease as $p$ increases.

As in the binomial situation it is easy to show that for $n > k$ we have

$$\frac{\partial P_p(N \geq n)}{\partial p} = -(n-1) \binom{n-2}{k-1} p^{k-1} (1 - p)^{n-k-1}$$

$$= \frac{\partial [1 - I_p(k, n-k)]}{\partial p} < 0,$$

(6)

For $n > k$: $P_p(N \geq n)$ decreases strictly from 1 to 0 as $p$ increases from 0 to 1.

For $n > k$ identity (6) $\implies$ $P_p(N \geq n) = 1 - I_p(k, n-k)$.

(7)
Usages of the Negative Binomial Distribution

Useful when only a limited number of successes can be tolerated.

A “success” could consist of a costly event, say destruction of the experimental unit, and only so many such units are available for running the trials.

Shapiro and Gross (1981) cite the drilling for oil as an example. Success consists of finding a productive well. It is desired to drill as little as possible in a given area.

Random testing of software when working against a deadline.

Such random testing can either involve random selection of inputs according to some usage profile from a well defined input space or it could consist of a session with a random person using the program (a spreadsheet or word processing program) in a given task.

Each time a software run or session results in faulty behavior it requires finding and fixing the responsible bug.

Such fixes take time and only $k$ can be tolerated within a given time window.
Consider testing $H(p_0) : p = p_0$ against the alternative $A(p_0) : p < p_0$.

Since it will take longer to fill the quota of $k$ successes when $p$ is small, large observed values $N = n$ can be viewed as evidence against the hypothesis.

Thus we reject $H(p_0)$ at target significance level $\alpha$ when $N \geq n(p_0, \alpha)$, where $n(p_0, \alpha)$ is chosen as the smallest integer $n$ for which $P_{p_0}(N \geq n) \leq \alpha$.

Thus we have $P_{p_0}(N \geq n(p_0, \alpha)) \leq \alpha$ and $P_{p_0}(N \geq n(p_0, \alpha) - 1) > \alpha$.

Again exploit the duality between confidence sets $C(n)$ and tests of hypotheses.

We define the confidence set $C(n)$ in terms of $p$-values $p(n, p_0) = P_{p_0}(N \geq n)$, namely as the set of all acceptable hypotheses $H(p_0)$ or all $p_0$ for which the $p$-value $p(n, p_0) > \alpha$ leads to acceptance of $H(p_0)$:

$$C(n) = \{ p_0 : p(n, p_0) = P_{p_0}(N \geq n) > \alpha \}.$$
Coverage Probabilities

\( C(N) \) as a random set has the following coverage property

\[
P_{p_0}(p_0 \in C(N)) = 1 - P_{p_0}(p_0 \notin C(N)) = 1 - P_{p_0}(N \geq n(p_0, \alpha)) \geq 1 - \alpha \ \forall p_0,
\]

Thus we consider \( C(N) \) as a 100\( \gamma \)% confidence set for the unknown parameter \( p_0 \).

We point out that \( \geq \) becomes \( = \) equality for some values of \( p_0 \), because there are values \( p_0 \) for which \( P_{p_0}(N \geq n(p_0, \alpha)) = \alpha \), since \( P_{p_0}(N \geq n) \) decreases continuously from 1 to 0 as \( p_0 \) increases from 0 to 1, i.e., takes on the value \( \alpha \) for some \( p_0 \). This can be accomplished for any value \( n > k \).

Thus the confidence coefficient (minimum coverage probability) of the confidence set \( C(N) \) is indeed \( \tilde{\gamma} = 1 - \alpha = \gamma \).
How to Calculate Upper Confidence Bounds

For $n > k$ the $p$-value $P_{p_0}(N \geq n)$ is continuous and strictly decreasing in $p_0$

$$\implies C(n) = [0, \tilde{p}_U(\gamma, n, k)], \text{ where } \tilde{p}_U(\gamma, n, k) = \tilde{p}_U(1 - \alpha, n, k)$$

is the unique value $p$ that solves

$$P_p(N \geq n) = \sum_{i=0}^{k-1} \binom{n-1}{i} p^i (1 - p)^{n-1-i} = \alpha = 1 - \gamma. \quad (8)$$

For $n = k$ equation (8) has no solution since $P_p(N \geq k) = 1$ for all $p$.

From the definition of $C(n)$ it follows directly that $C(k) = [0, 1]$.

In that special case define $\tilde{p}_U(\gamma, k, k) = 1$.

For $N = n > k$ use the Beta distribution identity (7) to calculate

$$\tilde{p}_U(\gamma, n, k) = \text{BETAINV}(\gamma, k, n - k) = \text{qbeta}(\gamma, k, n - k)$$
An Example, Properties and Special Cases

Example: \( k = 25, n = 1200 \) and \( \gamma = .95 \Rightarrow \tilde{p}_U(.95, 1200, 25) = .028036 \)

\[
(8) \Rightarrow 1 = \tilde{p}_U(\gamma, k, k) > \tilde{p}_U(\gamma, k + 1, k) > \ldots > \tilde{p}_U(\gamma, n, k) > \ldots \searrow 0 \quad \text{as } n \to \infty.
\]

At \( p = \tilde{p}_U(\gamma, n, k) \), \( n > k \), the coverage probability is exactly equal to \( \gamma \).

For \( k = 1 \)

\[
\tilde{p}_U(\gamma, n, 1) = 1 - (1 - \gamma)^{1/(n-1)}.
\]

useful for large \( n \). For \( \gamma = .95 \) the upper confidence bound becomes

\[
\tilde{p}_U(.95, n, 1) = 1 - (.05)^{1/(n-1)} = 1 - \exp \left[ \frac{\log(.05)}{n - 1} \right] \approx 1 - \exp \left[ -\frac{3}{n - 1} \right] \approx \frac{3}{n - 1},
\]

another instance of the Rule of Three. The last \( \approx \) is only valid for large \( n \).

The \( n - 1 \) in the denominator is the number of failures (the only random aspect here) that must precede the one success, that is assumed to happen a priori.

\[
n = k + 1 \implies \tilde{p}_U(\gamma, k + 1, k) = \gamma^{1/k} \approx 1. \quad \text{This case is of less practical interest.}
\]
Test the hypothesis $H(p_0) : p = p_0$ against the alternative $A(p_0) : p > p_0$.

Under $A(p_0)$ the quota of $k$ successes is filled faster than under $H(p_0)$.

$\Rightarrow$ Small values of $N = n$ will serve as evidence against the hypothesis.

The level $\alpha$ test rejects $H(p_0)$ whenever the $p$-value $p(n, p_0) = P_{p_0}(N \leq n) \leq \alpha$.

The duality between tests and confidence sets $\Rightarrow \gamma = 1 - \alpha$ level confidence set

$$C(n) = \{p_0 : P_{p_0}(N \leq n) > \alpha\} \quad \text{with} \quad P_{p_0}(p_0 \in C(N)) \geq 1 - \alpha \quad \forall p_0,$$

where $\geq 1 - \alpha$ becomes $= 1 - \alpha$ for some values of $p_0$. 
Calculation of $\tilde{p}_L(\gamma, n, k)$

$P_{p_0}(N \leq n)$ is continuous and strictly increasing in $p_0 \Rightarrow C(n) = (\tilde{p}_L(\gamma, n, k), 1]$, where $\tilde{p}_L(\gamma, n, k)$ is the unique value of $p$ that solves

$$P_p(N \leq n) = 1 - P_p(N \geq n + 1) = 1 - \sum_{i=0}^{k-1} \binom{n}{i} p^i (1 - p)^{n-i} = \alpha = 1 - \gamma.$$ 

Thus we can treat $\tilde{p}_L(\gamma, n, k)$ as a 100$\gamma$% lower confidence bound for $p$.

$$(7) \implies \tilde{p}_L(\gamma, n, k) = \text{BETAINV}(1 - \gamma, k, n - k + 1) = q\text{beta}(1 - \gamma, k, n - k + 1).$$

Example: $k = 5, n = 30$ and $\gamma = .95 \Rightarrow \tilde{p}_L(.95, 5, 30) = .068056.$
Special Cases

\[ k = 1 \implies \tilde{p}_L(\gamma, 1, n) = 1 - \gamma^{1/n} \approx 0 \text{ for } n = 1, 2, \ldots, \]

of not of much practical use.

\[ k = n \implies \tilde{p}_L(\gamma, n, n) = (1 - \gamma)^{1/n}. \]

For \( \gamma = .95 \) this becomes

\[ \tilde{p}_L(.95, n, n) = (1 - .95)^{1/n} \approx \exp(-3/n) \approx 1 - \frac{3}{n}, \]

another instance of the Rule of Three.

Here the last approximation is only valid for large \( n = k \).

Of course, using a large \( k \) only makes sense when \( p \approx 1 \), i.e., successes are accumulated quickly so that we wind up with \( k \) successes in the first \( k = n \) trials.

This is akin to seeing a lot of failures before seeing the first success, when reversing the role of successes and failures.
Confidence Intervals for $p$

The lower and upper bounds for $p$, i.e., $\tilde{p}_L(1 - \alpha/2, n, k)$ and $\tilde{p}_U(1 - \alpha/2, n, k)$,

can be combined into a confidence interval

$$(\tilde{p}_L(1 - \alpha/2, n, k), \tilde{p}_U(1 - \alpha/2, n, k))$$

at nominal level $\gamma = 1 - \alpha$.

Typically the confidence coefficient is $\tilde{\gamma} > 1 - \alpha = \gamma$. 
Bounding $N$ by Using $\tilde{N} = \min(N, n^*)$

$N$ is unbounded. This could easily lead to a very large $N$ when $p$ is very small.

When bounding $p$ from above one may want to put a limit $n^* > k$ on $N$ so that the possibility of a very small $p$ does not degenerate into squandering valuable resources, namely time and experimental units involved in the Bernoulli trials.

Having many trials without achieving the full quota should still lead to very effective upper bounds for $p$.

Not much will change when deriving confidence bounds for $p$ based on $\tilde{N} = \min(N, n^*)$.

$\tilde{N}$ is limited to the integers from $k$ to $n^*$. We also note that for $n = k, \ldots, n^*$

$$P_p(\tilde{N} \geq n) = P_p(\min(N, n^*) \geq n) = P_p(\{N \geq n\} \cap \{n^* \geq n\}) = P_p(N \geq n), \quad (9)$$
Upper Confidence Bounds Based on $\tilde{N}$

\( n > k: \quad P_p(\tilde{N} \geq n) \) is a continuous and strictly decreasing function in \( p \), and decreases from 1 to 0 as \( p \) increases from 0 to 1,

\( n = k: \quad P_p(\tilde{N} \geq k) = 1 \) for all \( p \).

As before, large values of \( \tilde{N} \) (although bounded by \( n^* \)) should cause us to reject \( H(p_0): p = p_0 \) in favor of the alternative \( A(p_0): p < p_0 \).

In view of equation (9) we find for \( p \) the same upper confidence bounds as for unbounded \( N \), namely for the degenerate case \( n = k \) we get \( \tilde{p}_U(\gamma, k, k) = 1 \) and for \( n = k + 1, \ldots, n^* \) we have

\[
\tilde{p}_U(\gamma, n, k) = q_{\text{beta}}(\gamma, k, n - k) = \text{BETAINV}(\gamma, k, n - k).
\]

There are only a finite number of such bounds and they satisfy

\[
1 = \tilde{p}_U(\gamma, k, k) > \tilde{p}_U(\gamma, k + 1, k) > \tilde{p}_U(\gamma, k + 2, k) > \ldots > \tilde{p}_U(\gamma, n^*, k) > 0.
\]
\( \tilde{p}_U(\gamma, n^*, k) \) is the smallest possible upper bound for \( p \) when using the bounded \( \tilde{N} \).

That is the price one has to pay for bounding \( N \) and it makes intuitive sense.

Without bounding \( N \) the bounds can get arbitrarily small.

How would one use this in practice?

Chose \( k \), say \( k = 1 \), and then \( n^* \) such that \( \tilde{p}_U(\gamma, n^*, k) \) is somewhat smaller than what is judged sufficiently small for \( p \), i.e., \( \tilde{p}_U(\gamma, n^*, k) \) is sufficiently small for the application at hand.

Obtaining smaller upper bounds, by raising the upper limit \( n^* \), would be overkill.
Lower Confidence Bounds Based on $\tilde{N}$

Note that for $k \leq n < n^*$

$$P_p(\tilde{N} \leq n) = P_p(\min(N, n^*) \leq n) = P_p(\{N \leq n\} \cup \{n^* \leq n\}) = P_p(N \leq n)$$ (10)

is again continuous and strictly increasing in $p$ and increases from 0 to 1 as $p$ increases from 0 to 1. For $n = n^*$ we have $P_p(\tilde{N} \leq n^*) = 1$ for all $p$.

Testing $H(p_0) : p = p_0$ against $A(p_0) : p > p_0$ reject for small $\tilde{N}$.

As in the unbounded case we obtain as lower bound for $k \leq n < n^*$

$$\tilde{p}_L(\gamma, n, k) = q\text{beta}(1 - \gamma, k, n - k + 1) = \text{BETAINV}(1 - \gamma, k, n - k + 1).$$

$n = n^* \Rightarrow \tilde{p}_L(\gamma, n^*, k) = 0$, since $P_p(\tilde{N} \leq n^*) = 1$ for all $p$ and thus the duality based confidence set in that case is

$$C(n^*) = \{p : P_p(\tilde{N} \leq n^*) > \alpha\} = [0, 1].$$
As in the unbounded case these one-sided bounds can be combined into confidence intervals, i.e.,

\[ (\tilde{p}_L(1 - \alpha/2, n, k), \tilde{p}_U(1 - \alpha/2, n, k)) \]

can be considered as a $100\gamma\% \ (\gamma = 1 - \alpha)$ confidence interval for $p$.

Typically, the confidence coefficient is $\tilde{\gamma} > \gamma$. 
The Probability of a Typo or Other Error

Although the book was definitely worth reading, I started to get annoyed by typos and other mistakes so that I decided to mark them.

I started with the use of “German” in place of “Germany” on page 59. I recall other such errors on prior pages but I was not going to reread those pages to mark them as well. Since page 59 was my decision point to start marking these errors I will not count that error on page 59.

The pages with marked errors after that are: 69, 81, 82, 92, 104, 107, 113, 114, 121 (121), 123 (123), 130 (130), 135, 139, 144, 145, 147, 154, 182 (182) (182), 198, 204, 205, 207, 213, 222, 229, 250, 251, 253, 253, 255 (255), 256. Parentheses indicate additional errors. The last page was 257.
We treat each page as a Bernoulli trial with “success” probability $p$ of containing an error (ignoring all the parenthetical additional counts)

We wish to give a 95% confidence interval for $p$.

We can do this based on the first 20 error pages found, starting with the first error on page 69 and the 20$^{th}$ on page 204. Thus we observed $N = 204 - 59 = 145$ and get as .95% confidence interval

$$(\tilde{p}_L(.975, 145, 20), \tilde{p}_U(.975, 145, 20))$$

$= (q_{beta}(.025, 20, 145 - 20 + 1), q_{beta}(.975, 20, 145 - 20))$

$= (0.0863, 0.1984)$.
Two More Analyses

If we limit ourselves to the next \( n^* = 100 \) pages or 20 errors, whichever comes first, we have \( \bar{N} = 100 = n^* \). The 95% confidence interval is

\[
(\hat{p}_L(.975, 100, 20), \hat{p}_U(.975, 100, 20)) = (0, q\text{beta}(.975, 20, 100 - 20)) = (0, 0.2834).
\]

Had we counted the number of errors in the first 100 pages, pp. 60-159, we could treat this count \((X = 17)\) as a binomial random variable with \( n = 100 \) and “success” probability \( p \). The 95% confidence interval in that case is

\[
(\hat{p}_L(.975, 17, 100), \hat{p}_U(.975, 17, 100)) = (q\text{beta}(.025, 17, 100 - 17 + 1), q\text{beta}(.975, 17 + 1, 100 - 17)) = (0.1023, 0.2582).
\]
Some Afterthoughts

The above interval \((0, 0.2834)\) when reaching the upper limit of 100 pages leaves an uneasy feeling with regard to the lower bound of 0.

We did not use the \(X = 17\) count reached when we stopped at \(n^* = 100\)

A lot of information was discarded by focussing on just \(\tilde{N}\) when \(\tilde{N} = n^*\) occurs.

This could have happened with \(X = 0, 1, 2, \ldots, 20\).

On intuitive grounds a smaller count of successes at the stopping state \(\tilde{N} = n^*\) should speak more strongly for a small \(p\).

The same concern about ignored information should be raised with respect to upper bounds.
Modified Approach for Bounded $\tilde{N}$

In performing such a truncated negative binomial experiment we should track two data quantities, namely $\tilde{N} = \min(N, n^*)$ and $X_{\tilde{N}}$.

$X_{\tilde{N}}$ counts the number of successes obtained by the time we stop observing.

For $\tilde{N} = n = k, \ldots, n^* - 1$ we have $X_{\tilde{N}} = k$.

For $\tilde{N} = n^*$ we could have stopped with $X_{\tilde{N}} = k, k - 1, \ldots, 0$ successes.

In terms of evidence for a small $p$ these situations can intuitively be ordered via

$$Y = \tilde{N} + k - X_{\tilde{N}}$$

with small $Y$ indicating a high value of $p$ and a large $Y$ indicating a small value of $p$.

When $\tilde{N} = k, k + 1, \ldots, n^* - 1$ then $Y$ takes on the values $y = k, k + 1, \ldots, n^* - 1$ (since then $X_{\tilde{N}} = k$)

$Y$ takes on the values $y = n^*, \ldots, n^* + k$ as $\tilde{N} = n^*$ and $X_{\tilde{N}} = X_{n^*} = k, \ldots, 1, 0$. 

82
Revised Lower Confidence Bounds

Testing the hypothesis $H(p_0) : p = p_0$ against $A(p_0) : p > p_0$ we should reject when $Y$ is too small. Duality principle $\implies \gamma = (1 - \alpha)$-level confidence set

$$C(y) = \{ p_0 : P_{p_0}(Y \leq y) > \alpha \}.$$  

$$P_p(Y \leq y) = \begin{cases} 
  P_p(N \leq y) & \text{for } y = k, \ldots, n^* \\
  P_p(X_{n^*} \geq n^* + k - y) & \text{for } y = n^*, n^* + 1, \ldots, n^* + k 
\end{cases}$$

is strictly increasing in $p$ for $y < n^* + k$ while $P_p(Y \leq n^* + k) = 1$ for all $p$.

Note that the two forms for $P_p(Y \leq n^*)$ agree.

$$y < n^* + k \implies C(y) = (\tilde{p}_L(\gamma, y, k), 1]$$ where $p = \tilde{p}_L(\gamma, y, k)$ solves $P_p(Y \leq y) = \alpha$.

Thus

$$\tilde{p}_L(\gamma, y, k) = \begin{cases} 
  \text{qbeta}(1 - \gamma, k, y - k + 1) & \text{for } y = k, \ldots, n^* \\
  \text{qbeta}(1 - \gamma, n^* + k - y, y - k + 1) & \text{for } y = n^*, n^* + 1, \ldots, n^* + k 
\end{cases}$$

and as in previous situations take $\tilde{p}_L(\gamma, n^* + k, k) = 0$ since $C(n^* + k) = [0, 1]$.  

83
Testing $H(p_0) : p = p_0$ against $A(p_0) : p < p_0$ reject $H(p_0)$ when $Y$ is too large.

Duality principle $\implies \gamma = (1 - \alpha)$-level confidence set

$$C(y) = \{ p_0 : P_{p_0}(Y \geq y) > \alpha \}.$$ 

$P_p(Y \geq y) = 1 - P_p(Y \leq y - 1)$ is strictly decreasing in $p$ for $y > k$

$\implies C(y) = [0, \tilde{p}_U(\gamma, y, k))$, where $p = \tilde{p}_U(\gamma, y, k)$ solves $P_p(Y \geq y) = \alpha$.

$$\tilde{p}_U(\gamma, y, k) = \begin{cases} 
q_{\text{beta}}(\gamma, k, y - k) & \text{for } y = k + 1, \ldots, n^* \\
q_{\text{beta}}(\gamma, n^* + k - y + 1, y - k) & \text{for } y = n^*, n^* + 1, \ldots, n^* + k
\end{cases}$$

For $y = k$ we take $\tilde{p}_U(\gamma, k, k) = 1$ since in that case we have $C(k) = [0, 1]$.

$$(\tilde{p}_L(1 - \alpha/2, y, k), \tilde{p}_U(1 - \alpha/2, y, k))$$ is a $(1 - \alpha)$-level confidence interval for $p$.

The confidence coefficient $\bar{\gamma}$ is typically greater than the nominal level $\gamma = 1 - \alpha$. 
Revisiting the previous example, where we limited ourselves to \( n^* = 100 \) inspected pages with just \( X = 17 \) pages found with errors, we have as observed value \( Y = y = 100 + 20 - 17 = 103 \) and we now get as 95% confidence interval for \( p \)

\[
(\tilde{p}_L(.975, 103, 20), \tilde{p}_U(.975, 103, 20) =
\]

\[
(qbeta(.025, 100 + 20 - 103, 103 - 20 + 1), qbeta(.975, 100 + 20 - 103 + 1, 103 - 20))
\]

\[
= (0.1022649, 0.2581754)
\]

This is certainly much improved over the interval \((0, 0.2834)\) based on \( \tilde{N} \) only.

The \( Y \)-based interval = \( X_n^* \)-based interval.

However, with \( Y \) the experiment could have stopped sooner if we had reached our quota of \( k = 20 \) prior to the set limit \( n^* = 100 \) inspected pages.
The Poisson Distribution and Monotonicity

For a Poisson random variable $X$ with mean $\lambda$ ($\lambda > 0$) we have

$$P_\lambda(X \leq k) = \sum_{i=0}^{k} \frac{\exp(-\lambda) \lambda^i}{i!}.$$ 

On intuitive grounds, a larger mean $\lambda$ should entail a decrease in $P_\lambda(X \leq k)$.

$$\frac{\partial P_\lambda(X \leq k)}{\partial \lambda} = -\sum_{i=0}^{k} \frac{\exp(-\lambda) \lambda^i}{i!} + \sum_{i=0}^{k} \frac{\exp(-\lambda) i \lambda^{i-1}}{i!}$$

$$= -\sum_{i=0}^{k} \frac{\exp(-\lambda) \lambda^i}{i!} + \sum_{i=0}^{k-1} \frac{\exp(-\lambda) \lambda^i}{i!} = -\frac{\exp(-\lambda) \lambda^k}{k!} < 0$$
Connection to the Gamma Distribution

By the Fundamental Theorem of Calculus we have

\[
\frac{\partial P_\lambda(X \leq k)}{\partial \lambda} = -\frac{\exp(-\lambda)\lambda^k}{k!} = \frac{\partial}{\partial \lambda} \int_\lambda^\infty \frac{\exp(-x)x^{k+1-1}}{\Gamma(k+1)} \, dx
\]

\[
\Rightarrow P_\lambda(X \leq k) = \sum_{i=0}^{k} \frac{\exp(-\lambda)\lambda^i}{i!} = \int_\lambda^\infty \frac{\exp(-x)x^{k+1-1}}{\Gamma(k+1)} \, dx
\]  \hspace{0.5cm} (11)

since both the left and right side converge to 1 as \( \lambda \to 0 \).

Here the righthand side of (11) is the right tail probability \( P(V \geq \lambda) \) of a Gamma random variable \( V \) with scale 1 and shape parameter \( k + 1 \).

\[
G_{k+1}(\lambda) = P(V \leq \lambda) = \int_0^\lambda \frac{\exp(-x)x^{k+1-1}}{\Gamma(k+1)} \, dx
\]

is also called incomplete Gamma function with parameter \( k + 1 \).
Uses of the Poisson Distribution

The Poisson distribution is useful for random variables $X$ that count incidents (accidents) over intervals of time $[0, T]$, or occurrences of defects or damage over surface areas $A$ or volumes $V$ (inclusions).

Given the number $x$ of such a count, the locations in time or surface or space of the $x$ incidents can be viewed as having been distributed according to a uniform distribution. Thus the often used description: Random failures.

In such a context (when counting incidents over a time interval $[0, T]$, or occurrences over an area $A$ or volume $V$) one usually expresses the mean $\lambda$ also as $\lambda = T \times \lambda_1$, or $\lambda = A \times \lambda_1$, or $\lambda = V \times \lambda_1$, where $\lambda_1$ would represent the mean of a count over a time interval of unit length (or an area or volume of measure 1). This is useful when trying to project counts to time intervals of length different from $T$, or when comparing such counts coming from different time intervals, with corresponding adjustments when dealing with areas or volumes.
Binomial Distribution $\approx$ Poisson Distribution for Small $p$

For small $p$: $\text{Binomial}(n, p) \approx \text{Poisson}(\lambda = np)$.

In fact, assuming $np_n = \lambda$ the limiting behavior of the binomial probabilities

$$
\binom{n}{x} p_n^x (1 - p_n)^{n-x} = \frac{(np_n)^x (1 - p_n)^n}{x!} \times \frac{(1 - p_n)^{-x} n(n - 1) \cdots (n - x + 1)}{n^x}
\exp(-\lambda) \frac{\lambda^x}{x!}
\quad\text{as}\quad n \to \infty
$$

is very instrumental in motivating the Poisson distribution.

Even though the above argument involves a limiting operation ($n \to \infty$) the actual approximation quality is governed by how small $p$ is and not by the magnitude of $n$.

In fact, there are much more general approximation results available.
Let $I_1, \ldots, I_n$ be independent Bernoulli r.v.s with $P(I_i = 1) = 1 - P(I_i = 0) = p_i$, $i = 1, \ldots, n$, i.e., they are not necessarily identically distributed.

The distribution of $W = I_1 + \ldots + I_n$ is called the Poisson-Binomial distribution and is quite complicated when the $p_i$ are not the same.

For small $p_i$ the distribution of $W$ is very well approximated by the Poisson distribution with mean $\lambda = \sum_{i=1}^{n} p_i = n\bar{p}$.

If $X \sim P(\lambda)$ we can approximate $P(W \in A)$ by $P(X \in A)$ for any set $A$. 
Approximation Error Bound

The total variation norm

\[ d_{TV}(W, X) = \sup_{A} |P(W \in A) - P(X \in A)| = \frac{1}{2} \sum_{j=0}^{\infty} |P(W = j) - P(X = j)| \]

is used to measure the quality of this approximation.

Barbour, Holst, and Janson (1992) give the following bound on \( d_{TV} \)

\[ d_{TV}(W, X) \leq \frac{1 - \exp(-\lambda)}{\lambda} \sum_{i=1}^{n} p_i^2 \leq \min(1, \lambda^{-1}) \sum_{i=1}^{n} p_i^2 \leq \max(p_1, \ldots, p_n) \]

The last inequality links up with our previous statement concerning the approximation quality in the binomial case.
Poisson-Binomial Approximation

- $n = 10$, $p = 0.05$
- $\lambda = 0.5$

$d_{TV} = \sup_A |P(X \in A) - P(Y \in A)|$

- $d_{TV} = 0.0119$
- $d_{TV}$ bound $= 0.0197$
Poisson-Binomial Approximation

\[ n = 100, \quad p = 0.05 \]
\[ \lambda = 5 \]

\[ d_{TV} = \sup_{A} | P(X \in A) - P(Y \in A) | \]
\[ d_{TV} = 0.0126 \]
\[ d_{TV} \text{ bound} = 0.0497 \]
Poisson-Binomial Approximation

\[ n = 1000, \ p = 0.05 \]
\[ \lambda = 50 \]
\[ d_{TV} = \sup_A |P(X \in A) - P(Y \in A)| \]
\[ d_{TV} = 0.0124 \]
\[ d_{TV \ bound} = 0.05 \]
Poisson-Binomial Approximation

- $n = 1000$, $p = 0.005$
- $\lambda = 5$

Probability density function:
- $X$: Binomial
- $Y$: Poisson

$d_{TV} = \sup_A |P(X \in A) - P(Y \in A)|$

$d_{TV} = 0.00123$
$d_{TV}$ bound $= 0.00497$
Commentary on Approximations

The previous 4 slides illustrate the approximation quality in the case of the binomial distribution \((p_1 = \ldots = p_n = p)\).

Note that \(n\) does not play much of a role, while the size of \(p\) does.

Also shown are the actual total variation norms in each case and the first upper bound on \(d_{TV}\), i.e., \([\frac{(1 - \exp(-\lambda))}{\lambda}] \times np^2 = (1 - \exp(-np)) \times p\).

The upper bounds for \(d_{TV}\) are very close to \(p\) when \(\lambda > 1\) and quite conservative (inflated by roughly a factor of 4) compared to the actually achieved \(d_{TV}\).

In the first plot we have \(\lambda = .5\). The bound on \(d_{TV}\) is different from \(p\) and is not quite as conservative compared to the actually achieved value of \(d_{TV}\).
R Program for Calculating Poisson-Binomial Probabilities

A deceptively simple but recursive R program for calculating \( P(W = k) \)

```r
poisbin = function (k,p) {
    #=================================================================
    # this function computes the probability of k success in n trials
    # with success probabilities given in the n-vector p.
    #=================================================================
    if(length(p)==0 | length(k)==0) return("invalid length of k or p")
    if(min(p*(1-p))<0) return("invalid p")
    if(k-round(k,0)>0) return(0)
    if(length(p)==1){
        if(k==0|k==1) {p^k*(1-p)^(1-k)}else{0}
    }else{
        p[1]*poisbin(k-1,p[-1])+(1-p[1])*poisbin(k,p[-1])
    }
}
```
Comments on R Program for Calculating $P(W = k)$

Note that there are about $2^n$ recursions, $n = \text{length of } (p_1, \ldots, p_n)$

$$P(W = k) = P\left(\sum_{i=1}^{n} I_i = k\right) = p_1 \times P\left(\sum_{i=2}^{n} I_i = k - 1\right) + (1 - p_1) \times P\left(\sum_{i=2}^{n} I_i = k\right)$$

and so on ...

Thus the time and memory requirements grow beyond practical limits very fast.

$2^{20} = 1048576!$

The next slide shows the results for $n = 16$ with the following probabilities:

$$p = .01, .01, .01, .02, .02, .03, .03, .03, .04, .04, .05, .05, .07.$$  

$2^{16} = 65536.$
Poisson-Binomial Approximation

\( p = 0.01, 0.01, 0.01, 0.02, 0.02, 0.03, 0.03, 0.03, 0.04, 0.04, 0.04, 0.05, 0.05, 0.06, 0.07 \)

\( \lambda = 0.54 \)

\[ d_{TV} = \sup_{A} | P(W \in A) - P(Y \in A) | \]

\( d_{TV} = 0.0102 \)

\( d_{TV} \text{ bound} = 0.0178 \)
Upper Confidence Bounds for $\lambda$

Test the hypothesis $H(\lambda_0) : \lambda = \lambda_0$ against the alternatives $A(\lambda_0) : \lambda < \lambda_0$.

Small values $x$ of $X$ can be viewed as evidence against the hypothesis $H(\lambda_0)$.

Reject $H(\lambda_0)$ at significance level $\alpha$ when the $p$-value $p(x, \lambda_0) = P_{\lambda_0}(X \leq x) \leq \alpha$.

The duality principle gives $C(x)$ as the set of all acceptable $H(\lambda_0)$, i.e.,

$$C(x) = \left\{ \lambda_0 : p(x, \lambda_0) = P_{\lambda_0}(X \leq x) > \alpha \right\}.$$

For the random set $C(X)$ we have again the following coverage probability property

$$P_{\lambda_0}(\lambda_0 \in C(X)) = 1 - P_{\lambda_0}(\lambda_0 \notin C(X)) \geq 1 - \alpha = \gamma$$

for any $\lambda_0 > 0$. Equality is achieved for some values of $\lambda_0$. 
Upper Confidence Bound Calculation

\( P_\lambda(X \leq x) \) is continuous in \( \lambda \) and strictly decreasing from 1 to 0.

\[ \implies C(x) = [0, \hat{\lambda}_U(\gamma, x)) \text{ where } \hat{\lambda}_U(\gamma, x) \text{ is the unique value of } \lambda \text{ that solves} \]

\[ P_\lambda(X \leq x) = \sum_{i=0}^{x} \frac{\exp(-\lambda)\lambda^i}{i!} = \alpha = 1 - \gamma = 1 - \int_{0}^{\lambda} \frac{\exp(-x)x^{k+1-1}}{\Gamma(k+1)} \, dx. \]

Get this upper bound \( \hat{\lambda}_U(\gamma, x) \) as the \( \gamma \)-quantile of the Gamma distribution with scale 1 and shape parameter \( x + 1 \)

\[ \hat{\lambda}_U(\gamma, x) = \text{GAMMAINV}(\gamma, x + 1, 1) = \text{qgamma}(\gamma, x + 1) \]

Thus we can treat \( \hat{\lambda}_U(\gamma, X) \) as a 100\( \gamma \)% upper confidence bound for \( \lambda \).
Example and Special Case

Example: $x = 2$ with $\gamma = .95 \implies \hat{\lambda}_U(.95, 2) = 6.295794$.

For the special case $x = 0$ there is an explicit formula for the upper bound,

$$\hat{\lambda}_U(\gamma, 0) = -\log(1 - \gamma).$$

$\gamma = .95 \implies \hat{\lambda}_U(.95, 0) = 2.995732 \approx 3,$

another instance of the Rule of Three.
Lower Confidence Bounds for $\lambda$

Test $H(\lambda_0) : \lambda = \lambda_0$ against the alternatives $A(\lambda_0) : \lambda > \lambda_0$.

Large values of $X$ would serve as evidence against the hypothesis $H(\lambda_0)$.

Observing $X = x$ reject $H(\lambda_0)$ whenever the $p$-value $p(x, \lambda_0) = P_{\lambda_0}(X \geq x) \leq \alpha$.

For any observable $x$ we define the confidence set $C(x)$ as consisting of all $\lambda_0$ corresponding to acceptable hypotheses $H(\lambda_0)$, i.e.,

$$C(x) = \left\{ \lambda_0 : p(x, \lambda_0) = P_{\lambda_0}(X \geq x) > \alpha \right\}.$$

The random set $C(X)$ has the desired coverage probability

$$P_{\lambda_0}(\lambda_0 \in C(X)) = 1 - P_{\lambda_0}(\lambda_0 \notin C(X)) \geq 1 - \alpha = \gamma \quad \text{for any } \lambda_0 > 0.$$

Here $\geq$ becomes $=$ for some $\lambda_0$. Thus the confidence coefficient $\bar{\gamma}$ of $C(X)$ is $\gamma$. 
Calculation of Lower Confidence Bounds for $\lambda$

$P_{\lambda_0}(X \geq 0) = 1$ for all $\lambda_0 \implies C(0) = (0, \infty)$.

$P_\lambda(X \geq x)$ is continuous in $\lambda$ and strictly increasing from 0 to 1 for $x > 0$.

$\implies C(x) = (\hat{\lambda}_L(\gamma, x), \infty)$ where $\hat{\lambda}_L(\gamma, x)$ is the unique value of $\lambda$ which solves

$$P_\lambda(X \geq x) = \sum_{i=x}^{\infty} \frac{\exp(-\lambda)\lambda^i}{i!} = G_x(\lambda) = 1 - \gamma.$$ 

For consistency we define $\hat{\lambda}_L(\gamma, 0) = 0$ to agree with the above form of $C(0)$.

Thus we can treat $\hat{\lambda}_L(\gamma, X)$ as a $100\gamma\%$ lower confidence bound for $\lambda$.

For $x > 0$ get $\hat{\lambda}_L(\gamma, x) = \text{GAMMAINV}(1 - \gamma, x, 1) = \text{qgamma}(1 - \gamma, x)$

For $x = 1$ get explicitly $\hat{\lambda}_L(\gamma, 1) = -\log(\gamma)$, since

$$P_\lambda(X \geq 1) = 1 - P_\lambda(X = 0) = 1 - \exp(-\lambda) = 1 - \gamma \implies \exp(-\lambda) = \gamma \implies \lambda = -\log(\gamma).$$
\hat{\lambda}_L(1 - \alpha/2, x) < \hat{\lambda}_U(1 - \alpha/2, x)

\hat{\lambda}_L(1 - \alpha/2, x) < \hat{\lambda}_U(1 - \alpha/2, x) \text{ for } x = 0, 1, 2, \ldots \text{ and } 0 < \alpha < 1.

Suppose to the contrary that \(\hat{\lambda}_L(1 - \alpha/2, x) \geq \hat{\lambda}_U(1 - \alpha/2, x)\) for some \(x\).

Then there exists a \(\lambda_0\) and \(x\) with \(\hat{\lambda}_L(1 - \alpha/2, x) \geq \lambda_0 \geq \hat{\lambda}_U(1 - \alpha/2, x)\).

For that \(\lambda_0\) and \(x\) we reject \(H(\lambda_0)\) when testing against \(A(\lambda_0) : \lambda > \lambda_0\)
or when testing it against \(\tilde{A}(\lambda_0) : \lambda < \lambda_0\).

\(\Rightarrow\) \(P_{\lambda_0}(X \geq x) \leq \alpha/2\) \quad \text{and} \quad P_{\lambda_0}(X \leq x) \leq \alpha/2\)

\(\Rightarrow\) \(1 > \alpha/2 + \alpha/2 \geq P_{\lambda_0}(X \geq x) + P_{\lambda_0}(X \leq x) = 1 + P_{\lambda_0}(X = x) > 1\)

which leaves us with a contradiction. Hence our assumption can’t be true.
Confidence Intervals for $\lambda$

$\hat{\lambda}_L(1 - \alpha/2, x) < \hat{\lambda}_U(1 - \alpha/2, x)$  for all $x = 0, 1, 2, \ldots$ and $0 < \alpha < 1$

$\implies P_\lambda(\hat{\lambda}_L(1 - \alpha/2, x) < \lambda < \hat{\lambda}_U(1 - \alpha/2, x))$

$= 1 - [P_\lambda(\lambda \leq \hat{\lambda}_L(1 - \alpha/2, x) \cup \hat{\lambda}_U(1 - \alpha/2, x) \leq \lambda)]$

$= 1 - [P_\lambda(\lambda \leq \hat{\lambda}_L(1 - \alpha/2, x)) + P_\lambda(\hat{\lambda}_U(1 - \alpha/2, x) \leq \lambda)]$

$\geq 1 - [\alpha/2 + \alpha/2] = 1 - \alpha = \gamma.$

Thus $(\hat{\lambda}_L(1 - \alpha/2, x), \hat{\lambda}_U(1 - \alpha/2, x))$ is a $100\gamma\%$ level confidence interval for $\lambda$.

Its confidence coefficient usually is $\tilde{\gamma} > \gamma$, for same reasons given previously.
For small \( p \) the binomial distribution of \( X \) is well approximated by the Poisson distribution with mean \( \lambda = np \).

Thus confidence bounds for \( p = \lambda/n \) can be based on those obtained via the Poisson distribution, namely by using \( \hat{\lambda}_U(\gamma,k)/n \) and \( \hat{\lambda}_L(\gamma,k)/n \).

A typical application would concern the number \( X \) of well defined, rare incidents (crashes or part failures) in \( n \) flight cycles in a fleet of airplanes.

Here \( p \) would denote the probability of such an incident during a particular flight.

Typically \( p \) is very small and \( n \), as accumulated over the whole fleet, is very large.
Aircraft Accidents

Accident Rates by Airplane Type

** The Comet, CV-880/990, Caravelle, Mercure, Trident & VC-10 are no longer in commercial service, and are combined in the "Not Flying" bar.
* These types have accumulated fewer than 1 million departures.
Accident data on commercial jet aircraft are updated yearly at

This summary provides ample opportunities for applying the confidence bound methods developed so far.

These reports do not show such bounds.

The previous slide shows a page on hull loss accidents from the 2001 report, still showing the Concorde line (no longer in 2005 report).

The next slide shows a version with confidence bounds.

Note how the confidence margins tighten as the number of accidents and the number of flights per aircraft model increase.

Details on Upper Confidence Bounds Calculation

95% upper confidence bounds were calculated based on the Poisson distribution and based on the binomial distribution.

\[ x = \text{# of hull losses and rate } \rho = \text{# of losses per 1 million departures} \]

\[ \rightarrow n = \text{# of departures during which each aircraft model was tracked:} \]

\[
\frac{\rho}{1000000} = \frac{x}{n} \quad \implies \quad n = \frac{x \times 1000000}{\rho} \quad \text{with rounding to the nearest integer.}
\]

For the Concorde: \( x = 1, \rho = 12.02 \), hence \( n = \frac{1000000}{12.02} \approx 83195 \).

\( p \) = probability of a hull loss/departure. Poisson approximation model with \( \lambda = np \)

\[
\hat{\lambda}(0.95, 1) = qgamma(0.95, 1 + 1) = 4.743865
\]

which converts to an upper bound

\[
\hat{p}_U(0.95, 1, n) = \frac{\hat{\lambda}(0.95, 1)}{n} = \frac{\hat{\lambda}(0.95, 1) \times \rho}{1 \times 1000000} = \frac{57.02125}{1000000} \quad \text{for } p .
\]
If we use a binomial based approach directly we get

$$\hat{p}_U(0.95, 1, n) = \text{qbeta}(0.95, 1 + 1, n - 1) = 5.701975 \times 10^{-5} = \frac{57.01975}{1000000}$$

which agrees with the previous value quite well.

In fact, all such computations for binomial based 95% upper bounds and corresponding Poisson based upper bounds agree to two decimal places.

Thus it suffices to show just one upper bound column in the following Table.

</table>
Hypergeometric Distribution

Randomly sample \( n \) items without replacement from a finite population of \( N \) items containing \( D \) defective and \( N - D \) non-defective items.

We observe the number \( X \) of defective items in the sample.

Rather than focusing on defective items they may be special items of interest.

A simple counting argument gives the probability function \( p(x) \) of \( X \) as

\[
p(x) = P_D(X = x) = \frac{D \binom{N-D}{n-x}}{\binom{N}{n}} \quad \text{for} \quad \max(n - N + D, 0) = D_m \leq x \leq D_M = \min(D, n)
\]

with \( p(x) = 0 \) otherwise. Its cumulative distribution function is

\[
F_D(x) = P_D(X \leq x) = \sum_{i=D_m}^{x} p(i) \quad \text{for} \quad D_m \leq x \leq D_M
\]

while \( F_D(x) = 0 \) for \( x < D_m \) and \( F_D(x) = 1 \) for \( x \geq D_M \).
Monotonicity Property

We expect that $F_D(x) = P_D(X \leq x) \searrow$ or $P_D(X \geq x) \nearrow$ as $D \nearrow$.

Think of an urn containing $D$ red, 1 pink, and $N - D - 1$ white balls.

Let $X = \#$ of red balls in the grab when the pink ball is viewed as white.
Let $Y = \#$ of red balls in the grab when the pink ball is viewed as red.

Show $P_D(X \geq x) < P_D(Y \geq x) = P_{D+1}(X \geq x)$ provided $D_m + 1 \leq x \leq D_M$.

There are $\binom{N}{n}$ possible grabs or samples of size $n$ from this urn.

We divide these different grabs into those (set $A$) that contain the pink ball and those (set $B$) that do not.

For all grabs $\omega \in B$ we have $X(\omega) = Y(\omega)$.
For all grabs $\omega \in A$ we have $Y(\omega) = X(\omega) + 1$. 

115
Monotonicity Property (cont.)

\[ P_D(\{X(\omega) = x - 1\} \cap A) > 0 \quad \text{for} \quad D_m + 1 \leq x \leq D_M \]

since for a grab \( \omega \in \{X(\omega) = x\} \cap A \) we have not yet reached the minimum number of red balls, thus we can replace a red ball in \( \omega \) with a white one from \( \{\omega\}^c \).

\[ \implies P_D(\{X(\omega) \geq x\} \cap A) < P_D(\{X(\omega) \geq x - 1\} \cap A) \]

\[ \implies P_D(X \geq x) = P_D(\{\omega : X(\omega) \geq x\} \cap A) + P_D(\{\omega : X(\omega) \geq x\} \cap B) \]
\[ = P(\{\omega : X(\omega) \geq x\} \cap A) + P(\{\omega : Y(\omega) \geq x\} \cap B) \]
\[ < P_D(\{\omega : X(\omega) \geq x - 1\} \cap A) + P_D(\{\omega : Y(\omega) \geq x\} \cap B) \]
\[ = P_D(\{\omega : Y(\omega) \geq x\} \cap A) + P_D(\{\omega : Y(\omega) \geq x\} \cap B) \]
\[ = P_D(Y \geq x) = P_{D+1}(X \geq x) \quad \text{q.e.d.} \]
Upper Confidence Sets

We view small values of $X$ as evidence against the hypothesis $H(D_0) : D = D_0$
when testing it against the alternative $A(D_0) : D < D_0$.

Thus we reject $H(D_0)$ when the $p$-value $p(x,D_0) = P_{D_0}(X \leq x) \leq \alpha = 1 - \gamma$.

The corresponding confidence set consists of all acceptable $H(D_0)$ at level $\alpha$, i.e.,

$$C(x) = \{D_0 : p(x,D_0) = P_{D_0}(X \leq x) > \alpha\}.$$  

We have the following coverage probability property for the random set $C(X)$

$$P_{D_0}(D_0 \in C(X)) = 1 - P_{D_0}(D_0 \notin C(X)) \geq 1 - \alpha = \gamma.$$  

The parameter $D$ is discrete $\Rightarrow$ minimum coverage probability is usually $> \gamma$, except for some select set of $\gamma$. 
For $x < n$ this $p$-value $p(x, D_0) = P_{D_0}(X \leq x)$ is decreasing from 1 to 0 with increasing $D_0$, and it is strictly decreasing while $0 < p(x, D_0) < 1$.

$\implies$ there exists a unique largest $D_0$ with $p(x, D_0) = P_{D_0}(X \leq x) > \alpha$.

We denote this value by $\hat{D}_U(\gamma, x)$.

For $x = n$ we have $p(n, D_0) = P_{D_0}(X \leq n) = 1 > \alpha$ for all $D_0$.

Thus $C(n) = [0, N]$ and we define $\hat{D}_U(\gamma, n) = N$ in that case.

$\implies$ $C(x) = [0, \hat{D}_U(\gamma, x)]$. Note the closed form of the interval here.

Replace the lower bound 0 by $x$ since we saw that many in the sample.

$\implies$ $C(x) = [x, \hat{D}_U(\gamma, x)]$
$\hat{D}_U$ via the Function hypergeo.conf

Example: $N = 2500$, $n = 50$, $x = 11$ and $\gamma = .95$

> hypergeo.conf(11,50,2500,.95,type="upper",cc.flag=T)

$\begin{array}{ll}
\text{lower} & \text{upper} \\
11 & 841 \\
\end{array}$

$\begin{array}{ll}
\text{nominal} & \text{minimum} \\
0.9500000 & 0.9500011 \\
\end{array}$

hypergeo.conf $\rightarrow$ confidence coefficient $\bar{\gamma}$ (minimum coverage probability) when the logic flag cc.flag=T is set. Here $\bar{\gamma} = 0.9500011 \approx .95$.

$\hat{D}_U \rightarrow 95\%$ upper bound of $\hat{D}_U/N = 0.3364$ for the population proportion $p = D/N$. Based on binomial distribution get $\hat{p}_U = 0.3378$, not much different.
Lower Confidence Sets

Test $H(D_0): D = D_0$ against the alternative $A(D_0): D > D_0$

High values of $X$ can be viewed as evidence against the hypothesis $H(D_0)$.

Observing $X = x$ we reject $H(D_0)$ at level $\alpha$ whenever the $p$-value

\[ p(x, D_0) = P_{D_0}(X \geq x) \leq \alpha. \]

The corresponding confidence set is

\[ C(x) = \{D_0 : p(x, D_0) = P_{D_0}(X \geq x) > \alpha\} \]

\[ P_{D_0}(D_0 \in C(X)) = 1 - P_{D_0}(D_0 \notin C(X)) \geq 1 - \alpha = \gamma. \]

We usually have $> \gamma$ for all $D_0$, because of the discrete nature of the parameter $D_0$. 
Lower Confidence Bounds

$x > 0$: the $p$-value $P_{D_0}(X \geq x)$ increases from 0 to 1 as $D_0$ increases from 0 to $N$, it increases strictly as long as $0 < p(x, D_0) = P_{D_0}(X \geq x) < 1$

$\implies$ there is a smallest value of $D_0$ for which $P_{D_0}(X \geq x) > \alpha$. Denote it by $\hat{D}_L(\gamma, x)$.

$x = 0$: $P_{D_0}(X \geq 0) = 1$ for all $D_0$, $\implies C(0) = [0, N]$ and define $\hat{D}_L(\gamma, 0) = 0$.

$\implies C(x) = [\hat{D}_L(\gamma, x), N]$, which again has a closed form.

Thus we can consider $\hat{D}_L = \hat{D}_L(\gamma, X)$ as a $100\gamma\%$ lower confidence bound for $D$.

Improve on the upper bound statement $N$ by replacing it by $N - (n - x)$, since we saw $n - x$ non-defective items in the sample.

This limits the number $D$ in the population by $N - (n - x)$ from above for sure.

$\implies C(x) = [\hat{D}_L(\gamma, x), N - (n - x)]$. 
Example take $N = 2500$, $n = 50$, $x = 11$, and $\gamma = .95$ and obtain

```r
> hypergeo.conf(11, 50, 2500, .95, type="lower", cc.flag=T)
$bounds
lower upper
 324   2461
```

$confidence

nominal minimum
0.9500000 0.9500011

i.e., we get $\hat{D}_L = \hat{D}_L(\gamma, 11) = 324$ as 95\% lower confidence bound for $D$.
Again the confidence coefficient was requested and is given as 0.9500011.

$\rightarrow \hat{D}_L(\gamma, 11)/N = 324/2500 = .1296$ as 95\% lower bound for $p = D/N$.

The corresponding binomial based lower confidence bound is $\hat{p}_L = 0.1286$. 

$\hat{D}_L$ via the Function `hypergeo.conf`
\[ \hat{D}_L(1 - \alpha/2, x) \leq \hat{D}_U(1 - \alpha/2, x) \]

\( D_0 = \hat{D}_U(1 - \alpha/2, x) \) is by definition the largest \( D \) such that \( P_D(X \leq x) > \alpha/2 \)

\( D_1 = \hat{D}_L(1 - \alpha/2, x) \) is the smallest \( D \) such that \( P_D(X \geq x) > \alpha/2 \) or such that \( P_D(X \leq x - 1) < 1 - \alpha/2 \).

\[ \implies \frac{\alpha}{2} \geq P_{D_0+1}(X \leq x) \geq P_{D_0}(X \leq x - 1) < 1 - \frac{\alpha}{2}, \]

where the last \(<\) holds because we can’t have \( \alpha/2 \geq 1 - \alpha/2 \), the first \(\geq\) follows from the definition of \( D_0 \), and the middle \(\geq\) holds generally, see next slide.

\( P_{D_0}(X \leq x - 1) < 1 - \alpha/2 \implies D_1 \leq D_0 \), using the alternate definition of \( D_1 \).
\[ P_{D-1}(X \leq x - 1) \leq P_D(X \leq x) \]

The above inequality holds quite generally for all \( x \) and \( D \).

Use again the urn with \( D - 1 \) red balls, one pink ball, and \( N - D \) white balls.

The set \( A \) consists of all those grabs of \( n \) balls that contain the pink ball. 
\( B \) consists of all grabs of \( n \) balls that don’t contain the pink ball.

\( X \) counts the number of red balls in the grab, interpreting pink as white. 
\( Y \) counts the number of red balls in the grab, interpreting pink as red.

We have \( X(\omega) = Y(\omega) \) for all grabs \( \omega \) in \( B \) and \( X(\omega) + 1 = Y(\omega) \) for all \( \omega \in A \).

\[ \Rightarrow \quad P_{D-1}(X \leq x - 1) = P_{D-1}(X \leq x - 1 \cap A) + P_{D-1}(X \leq x - 1 \cap B) \]
\[ = P_{D-1}(Y \leq x \cap A) + P_{D-1}(Y \leq x - 1 \cap B) \]
\[ \leq P_{D-1}(Y \leq x \cap A) + P_{D-1}(Y \leq x \cap B) \]
\[ = P_{D-1}(Y \leq x) = P_D(X \leq x) \] 
q.e.d.
A consequence of the previous inequality is that $\hat{D}_U(\gamma, x)$ and $\hat{D}_L(\gamma, x)$ are strictly increasing in $x$ in the allowable range.

Recall that $\hat{D}_U(\gamma, x)$ is the largest $D$ for which $P_D(X \leq x) > \alpha = 1 - \gamma$.

Using the above inequality, i.e., $P_{D+1}(X \leq x + 1) \geq P_D(X \leq x)$, we see that

$$P_{D+1}(X \leq x + 1) \geq P_D(X \leq x) > \alpha \implies \hat{D}_U(\gamma, x + 1) \geq \hat{D}_U(\gamma, x) + 1 > \hat{D}_U(\gamma, x).$$
Confidence Intervals

Since $\hat{D}_L(1 - \alpha/2, x) \leq \hat{D}_U(1 - \alpha/2, x)$ for any $x$ and $0 < \alpha < 1$

we may use $[\hat{D}_L(1 - \alpha/2, X), \hat{D}_U(1 - \alpha/2, X)]$ as a confidence interval

with coverage probability $\geq \gamma$, since

$$P_D(\hat{D}_L(1 - \alpha/2, X) \leq D \leq \hat{D}_U(1 - \alpha/2, X))$$

$$= 1 - P_D(D < \hat{D}_L(1 - \alpha/2, X) \cup \hat{D}_U(1 - \alpha/2, X) < D)$$

$$= 1 - [P_D(D < \hat{D}_L(1 - \alpha/2, X)) + P_D(\hat{D}_U(1 - \alpha/2, X) < D)]$$

$$\geq 1 - [\alpha/2 + \alpha/2] = \gamma.$$

The confidence coefficient $\tilde{\gamma}$ is typically $> \gamma$, due to the discrete nature of $D$

and because the one-sided bounds may not have minimum coverage probability

at the same $D$. 126
As in the binomial case we computed coverage probabilities as a function of $D$ for an example situation, namely for $n = 40$, $N = 400$, and $\gamma = .95$.

The results are shown on the following slides.

The functions used to produce these plots are `D.minimum.coverage.upper`, `D.minimum.coverage.lower`, and `D.minimum.coverage.int`.

As pointed out before, there is no guarantee that the actual minimum coverage probability $\tilde{\gamma}$ equals the nominal value of $\gamma$, although we know $\tilde{\gamma} \geq \gamma$. 

Coverage Probabilities for $\hat{D}_U(.95, x)$

nominal confidence level = 0.95
population size $N = 400$
sample size $n = 40$
Coverage Probabilities for $\hat{D}_L(.95, x)$

nominal confidence level = 0.95
population size N = 400
sample size n = 40
Coverage Probabilities for \([\hat{D}_L(.975,x), \hat{D}_U(.975,x)]\)

- Nominal confidence level = 0.95
- Population size \(N = 400\)
- Sample size \(n = 40\)
Minimum Coverage Probabilities $\tilde{\gamma}$

$\tilde{\gamma} = .9503$ for one-sided bounds, $\tilde{\gamma} = 0.9534$ for the intervals.

In the case of one-sided bounds it can be shown that there is a distinct and quite rich set of $\gamma$ values for which the minimum coverage probability $\tilde{\gamma}$ equals $\gamma$.

We will show this here for upper bounds.

For each set of integers $D^*$ and $x^*$ with

$$0 < P_{D^*+1}(X \leq x^*) = \alpha(D^*, x^*) = \alpha^* < 1$$

we define $\gamma(D^*, x^*) = \gamma^* = 1 - \alpha^*$.

We then have $\hat{D}_U(\gamma^*, x^*) = D^*$ and $\tilde{\gamma}^* = \gamma^*$. 

131
\[ \hat{D}_U(\gamma^*, x^*) = D^* \quad \text{since} \quad P_{D^* + 1}(X \leq x^*) = \alpha^* \quad \text{and} \quad P_{D^*}(X \leq x^*) > \alpha^* , \]

the strict monotonicity property of \( P_D(X \leq x) \) with respect to \( D \) \( \implies \) the last >.

Since \( \hat{D}_U(\gamma^*, X) \) is strictly increasing in \( X \) and since \( \hat{D}_U(\gamma^*, x^*) = D^* \) we have

\[
P_{D^* + 1}(D^* + 1 > \hat{D}_U(\gamma^*, X)) = P_{D^* + 1}(D^* \geq \hat{D}_U(\gamma^*, X)) = P_{D^* + 1}(X \leq x^*) = \alpha^* \]

and hence

\[
P_{D^* + 1}(D^* + 1 \leq \hat{D}_U(\gamma^*, X)) = \gamma(D^*, x^*) \implies \bar{\gamma}(D^*, x^*) = \bar{\gamma}^* = \gamma^*. \]
Confidence Coefficient $\bar{\gamma}$ vs. Nominal $\gamma$ for Upper/Lower Bounds

Diagram showing the relationship between nominal $\gamma$ and minimum coverage $\bar{\gamma}$. The data points form a straight line indicating a direct correlation.
Confidence Coefficient $\bar{\gamma}$ vs. Nominal $\gamma$ for Intervals
Some Comments

In the case of upper/lower bounds the discrepancies between $\gamma$ and $\tilde{\gamma}$ appear to be small, with $\gamma = \tilde{\gamma}$ for many $\gamma$ over the short displayed range $[.97, .98]$.

Thus the discreteness of $D$ does not appear to be a serious issue, based on the examined case $n = 40, N = 400$.

For intervals the minimum coverage $\tilde{\gamma}$ shows much stronger deviations from $\gamma$.

This is due to the much wider zigzag swings within the coverage probabilities of one-sided bounds and the fact that minima may not be attained at the same $D$ for either one-sided bound.

Keep in mind that we need to distinguish between nominal $\gamma$, actual coverage probability that changes with $D$ and minimum coverage probability $\tilde{\gamma}$.

$\tilde{\gamma} = \gamma$ or $\tilde{\gamma} \approx \gamma$ for only a few values of $\gamma$ in the displayed range $[.94, .96]$.
The Classical Birthday Problem

The classical birthday problem is often presented in elementary probability courses.

The chance that $n$ random persons have birthdays on $n$ different days in the year is

$$P(D) = \frac{(365)_n}{365^n} = \frac{365(365 - 1) \cdots (365 - n + 1)}{365^n}$$

Thus the probability of at least one match is

$$P(M) = 1 - \frac{(365)_n}{365^n} \geq .5 \text{ for } n \geq 23.$$ 

This is assumes a non leap year and equal likelihoods of all 365 possible birthdays for all $n$ persons. Unequal birthday probabilities increase $P(M)$.

A student once asked the following question:

What is the chance of seeing at least one pair of matching or adjacent birthdays?
Matching or Adjacent Birthdays

First we find the number of ways of arranging $a = 365 - n$ $N$’s and $n$ $B$’s such that no two $B$’s are next to each other.

Set up the $a$ $N$’s next to each other and count how many ways we can place a $B$ between two $N$’s, with at most one such $B$ per gap. There are $(a - 1) + 1 = a$ such gaps, counting the gaps at the end as one joined wrap around gap.

There are $\binom{a}{n}$ ways to put $n$ $B$’s into the $a$ gaps, $n!$ birthday to person assignments.

Thus the probability of the event $A$, of getting $n$ birthdays at least one day apart, is

$$P(A) = \frac{n!}{365^n} \binom{365 - n}{n} = \frac{(365 - n)_n}{365^n}.$$  

Thus the probability of at least one matching or neighboring pair of birthdays is

$$P(A^c) = 1 - \frac{(365 - n)_n}{365^n}.$$  

Hence $P(A^c) = .5013$ for $n = 13$ and $P(A^c) = .895$ for $n = 23$. 

137
$P(A^c)$ Done Correctly

As pointed out to me by Tatiana Maravina, the above formula for $P(A)$ is incorrect.

Try to figure out why, aside from $P(A) = 365 \times 362/365^2 = 362/365$ for $n = 2$.

The correct formula is

$$P(A) = \binom{365 - n - 1}{n - 1} \frac{(n - 1)!365}{365^n} = \frac{(365 - 2n + 1)(365 - 2n + 2) \cdots (365 - 2n + n - 1)}{365^{n-1}}$$

365 ways to choose the birthday for person 1. There are $365 - n$ non-birthdays.

Use the remaining $n - 1$ birthdays to each fill one of the remaining $365 - n - 1$ gaps between the non-birthdays, $\binom{365-n-1}{n-1}$ ways. That fixes the $N-B$ pattern.

$(n - 1)!$ ways to assigns these birthdays to the remaining $(n - 1)$ persons.

$n = 14$ gives the smallest $n$ for which this $P(A) \geq .5$, in fact we get $P(A) = .5375$.

The next slide gives a visual comparison of these probabilities. The wrong and correct $P(A^c)$ don’t differ by much.
$P(M)$ and $P(A^c)$
The following problem arose in connection with the Inertial Upper Stage of the Military Space Program.

http://www.fas.org/spp/military/program/launch/ius.htm

\( n = 12 \) out of \( N = 200 \) parts (rocket motors) are to be tested in some form.

It is expected that all tested items will be non-defective. Find \( \hat{D}_U(\gamma, 0) \).

A ship-set of \( k = 16 \) parts is randomly chosen from the population of \( N \) to serve as stage separation motors.

Find lower bound \( \hat{p}_1 \) for the probability that this ship-set contains \( \leq 1 \) defective.

After addressing this problem it was pointed out that the 16 parts will be arranged in a circular pattern. All that matters is that no two defective parts be placed next to each other. Find lower confidence bound \( \hat{p}_2 \) for the probability that no two defective parts are placed next to each other.
Assumptions and Notation

This does not quite match the birthday problem since we cannot have two defective parts in the same position.

However, we can base probability calculations on a similar counting strategy.

We assume that the $n = 12$ parts are selected randomly from the population.

The same is assumed for the ship-set of $k = 16$, where we assume that the $n = 12$ tested ones were previously returned to the population.

The $k = 16$ parts are arranged in a random circular order.

$D = \# \text{ of defective parts in the population of } N \text{ parts.}$

$X = \# \text{ of defective items in the tested sample of } n = 12.$ We expect $X = 0.$
Approach

Based on $X = 0$ what kind of upper confidence bounds $\hat{D}_U(\gamma, 0)$ can we get?

Recall that $\hat{D}_U(\gamma, 0) = D \iff P_D(X = 0) > \alpha = 1 - \gamma$ and $P_{D+1}(X = 0) \leq \alpha$.

By choosing the $\gamma$ values judiciously as $\gamma_D = 1 - P_{D+1}(X = 0)$, i.e., as high as possible for each value of $D$, we can associate the highest possible confidence level with each $\hat{D}(\gamma, 0) = D$.

Note that any $\gamma > \gamma_D$ would result in $P_{D+1}(X \leq 0) > 1 - \gamma$ and thus in $\hat{D}_U(\gamma, 0) \geq D + 1$.

Also note that this choice of $\gamma_D$ ensures that $\bar{\gamma} = \gamma_D$, as was shown previously.

Upper bound on $D \implies$ lower bounds $\hat{p}_1$ and $\hat{p}_2$.

</table>
Interpretation

We can get $\hat{D}(\gamma, 0) = 10$ with varying confidence levels, depending on the strength of testing evidence, i.e., for how big a sample of size $n$ we observed 0 failures.

By choosing $n$ higher we can attach higher confidence to the stated bounds $\hat{p}_1$ and $\hat{p}_2$, provided we still stay with 0 failures among the larger tested sample of size $n$.

We cannot force 0 failures and the confidence level $\gamma$ only has meaning in the context of a random upper bound $\hat{D}_U(\gamma, X)$.

Using this approach we pretend to be clairvoyant in saying $X = 0$ will be observed.

This method is useful as a planning tool when weighing confidence against the cost of testing, in view of expected results ($X = 0$).
Let $Y$ denote the random number of defectives in the shipset sample of $k = 16$.

Then the probability of seeing at most 1 defective in that sample is

$$Q(D) = P_D(Y \leq 1) = P_D(Y = 0) + P_D(Y = 1) = \frac{D}{N} \frac{(N-D)}{k-0} + \frac{D}{N} \frac{(N-D)}{k-1}.$$ 

Since this probability decreases with increasing $D$ we can take $\hat{p}_1 = Q(\hat{D}_U(\gamma, 0))$ as lower bound on $Q(D)$ with same confidence level as was associated with $\hat{D}_U(\gamma, 0)$. 

145
Lower Bound $\hat{p}_2$

To motivate the lower bound $\hat{p}_2$ we need to derive a formula for the probability that no two defective parts will be placed next to each other in a circular arrangement of $k = 16$ parts. This probability can be expressed as follows

$$Q^*(D) = P_D(Y = 0) + P_D(Y = 1) + P_D(Y = 2)P(A_2)$$

$$+ P_D(Y = 3)P(A_3) + \ldots + P_D(Y = 8)P(A_8),$$

where $A_y$ is the event that no two defective parts will be placed next to each other when $y$ defective parts and $k - y$ non-defective parts are arranged randomly in a circular pattern.

We have

$$P_D(Y = y) = \frac{\binom{D}{y} \binom{N-D}{k-y}}{\binom{N}{k}}$$

and

$$\psi(y) = P(A_y) = \frac{\binom{k-y}{y}}{\binom{k-1}{y}}.$$ 

with $\psi(y) \downarrow$ in $y$ and

$$Q^*(D) = E_D(\psi(Y)) \downarrow \text{ in } D \implies \hat{p}_2 = Q^*(\hat{D}_U(\gamma, X)).$$
\[ \psi(y) = P(A_y) \]

Label the \( y \) defective parts \( F_1, \ldots, F_y \) and the \( m = k - y \) non-defective parts by \( G_1, \ldots, G_m \). There are \( k! \) ways of arranging these \( k \) parts in a circular pattern, all equally likely. How many of these patterns have no two \( F \)'s next to each other?

\( G_1 \) can be in any of the \( k \) places. We can arrange the remaining \( m - 1 \) \( G \)'s in \((m - 1)!\) ways to form some circular sequence order of \( G \)'s.

Next we place the \( y \) \( F \)'s between the \( G \)'s so that only one \( F \) goes into any one gap.

There are \( \binom{m}{y} \) ways of designating the gaps to receive just one \( F \) each.

There are \( y! \) ways of arranging the order of the \( y \) \( F \)'s.

\[ \implies \quad P(A_y) = \frac{k(k - y - 1)! \binom{k-y}{y} y!}{k!} = \frac{\binom{k-y}{y}}{\binom{k-1}{y}}. \]

Note that \( P(A_0) = P(A_1) = 1 \) and \( P(A_y) = 0 \) for \( y > k - y \).
\[ \psi(y) = P(A_y) \downarrow \]

\[
\frac{P(A_{y+1})}{P(A_y)} = \frac{\binom{k-y-1}{y+1}}{\binom{k-1}{y+1}} \frac{\binom{k-y}{y}}{\binom{k-1}{y}}
\]

\[
= \frac{(k-y-1)! (y+1)!(k-y-2)!}{(y+1)!(k-2(y+1))!} \frac{y!(k-2y)!}{(k-y)!} \frac{(k-1)!}{y!(k-y-1)!}
\]

\[
= \frac{(k-2y)(k-2y-1)}{(k-y)(k-y-1)} < 1
\]

\[\iff (k-2y)(k-2y-1) < (k-y)(k-y-1)\]

\[\iff -2k + 3y + 1 < 0\]

which is true for \( y = 1, \ldots, k/2 \).
\[ Q^*(D + 1) = E_{D+1}(\psi(Y)) \leq E_D(\psi(Y)) = Q^*(D) \]

\[ p_{D+1}(y) = p_{D+1}(Y = y) = \frac{(D+1) \binom{N-D-1}{k-y}}{\binom{N}{k}} < \frac{(D) \binom{N-D}{k-y}}{\binom{N}{k}} = p_D(y) \iff y < \frac{k(D+1)}{N+1} . \]

Let \( A = \{ y : p_{D+1}(Y = y) < p_D(Y = y) \} \) and \( B = \{ y : p_{D+1}(Y = y) > p_D(Y = y) \} \)

\[ A < k(D+1)/(N+1) < B. \quad \psi(y) \downarrow \implies a = \inf_A \psi(y) \geq \sup_B \psi(y) = b \implies \]

\[ E_{D+1}[\psi(Y)] - E_D[\psi(Y)] = \sum_{y \in A} \psi(y) (p_{D+1}(y) - p_D(y)) + \sum_{y \in B} \psi(y) (p_{D+1}(y) - p_D(y)) \]

\[ \leq a \sum_{y \in A} (p_{D+1}(y) - p_D(y)) + b \sum_{y \in B} (p_{D+1}(y) - p_D(y)) \]

\[ = (b - a) \sum_{y \in B} (p_{D+1}(y) - p_D(y)) \leq 0 \]

since

\[ 0 = \sum_y (p_{D+1}(y) - p_D(y)) = \sum_y (p_{D+1}(y) - p_D(y)) + \sum_y (p_{D+1}(y) - p_D(y)) \]

and thus \[ \sum_{y \in A} (p_{D+1}(y) - p_D(y)) = - \sum_{y \in B} (p_{D+1}(y) - p_D(y)) . \]
How do we interpret the results in the previous Table in relation to $\hat{p}_1$ and $\hat{p}_2$?

For the originally proposed sample size $n = 12$ for testing, we can be 82.1% confident that $D \leq 25$ and that the probability of having less than two defective items in the ship-set of $k = 16$ is at least .377, not a very happy state of affairs.

This is based on the assumption that we see indeed no defective items in the sample of $n = 12$.

After qualifying that the more than one defective parts only matter when at least two are adjacent, we can be 82.1% confident that the probability of seeing no such adjacency is at least .80, which may still not be satisfactory.
p1p2.hat for Computing $\hat{p}_1$ & $\hat{p}_2$

```r

0.9503716
```
Adjusting $\gamma$

When changing $\gamma$ to a value that comes closer to $\bar{\gamma} = 0.9503716$ we get

```r
> plp2.hat(0,40,.9503716,200,16)
```

... everything else staying the same

$\hat{\gamma}$

minimum

0.9503716

$\Rightarrow$ the highest possible confidence level $\gamma = \bar{\gamma}$ for that value of $\hat{D}_U(0, \gamma) = D.U = 12.$
What if $X = x > 0$?

In that case the upper bound $\hat{D}_U(\gamma, x)$ will increase.

$\hat{p}_1 = Q(\hat{D}_U(\gamma, x))$ and $\hat{p}_2 = Q^*(\hat{D}_U(\gamma, x))$ will decrease.

However, we should not return defective items into the population.

$\Rightarrow \ N \rightarrow N' = N - x \ and \ D \rightarrow D' = D - x$

Should use $\hat{D}'_U(\gamma, x) = \hat{D}_U(\gamma, x) - x$ when plugging into $Q(D)$ and $Q^*(D)$

i.e., use $\hat{p}_1 = Q(\hat{D}'_U(\gamma, x))$ and $\hat{p}_2 = Q^*(\hat{D}'_U(\gamma, x))$
Example with $X = 1$

```r
> plp2.hat(1, 40, .9503716, 200, 16)

  minimum
0.9503716
```
Final Warning

$X = 1$ results in lower confidence bounds for $Q(D)$ and $Q^*(D)$.

Do not trade off some of the confidence level (lowering it) to increase the lower bounds $\hat{p}_1$ or $\hat{p}_2$.

This would negate the theoretical underpinnings of confidence bounds.

The confidence level should not become random (a function of $X$).

This is no empty warning. I have experienced this kind of ingenuity from engineers.

Webster’s: “engineer” and “ingenuity” have the same Latin origin: ingenium.
Assume $X \sim \text{Poisson}(\lambda)$ and $Y \sim \text{Poisson}(\mu)$ are independent.

We are interested in confidence bounds for $\rho = \lambda/\mu$.

If these Poisson distributions represent approximations of binomials for small “success” probabilities $\pi_1$ and $\pi_2$, i.e., $\lambda = n_1 \pi_1$ and $\mu = n_2 \pi_2$, then confidence bounds for the ratio $\rho = \lambda/\mu = (n_1 \pi_1)/(n_2 \pi_2)$ are equivalent to confidence bounds for $\kappa = \pi_1/\pi_2$, since $n_1$ and $n_2$ are typically known.

The classical method for getting confidence bounds for $\rho$ is to view $Y$ in the context of the total observed count $X + Y$, i.e., consider the conditional distribution of $Y$ given $T = X + Y = t$. 

156
Conditional Distribution of $Y$ Given $X + Y = t$

$$P(Y = k|X + Y = t) = \frac{P(Y = k, X + Y = t)}{P(X + Y = t)} = \frac{P(Y = k, X = t - k)}{P(X + Y = t)}$$

$$= \frac{P(Y = k)P(X = t - k)}{P(X + Y = t)}$$

$$= \frac{[\exp(-\mu)\mu^k]/k! \times [\exp(-\lambda)\lambda^{t-k}]/(t-k)!}{\exp(-[\mu+\lambda])[\mu+\lambda]^t/t!}$$

$$= \binom{t}{k} p^i(1 - p)^{t-i},$$

where $p = \mu/(\lambda + \mu) = 1/(1 + \rho)$.

Here we used the fact that $X + Y$ has a Poisson distribution with mean $\lambda + \mu$. 

157
\[ X + Y \sim \text{Poisson}(\lambda + \mu) \]

\[
P(X + Y = t) = \sum_{i=0}^{t} P(X = i \cap Y = t - i)
\]

\[
= \sum_{i=0}^{t} P(X = i) \times P(Y = t - i)
\]

\[
= \sum_{i=0}^{t} \frac{\exp(-\lambda)\lambda^i}{i!} \times \frac{\exp(-\mu)\mu^{t-i}}{(t-i)!}
\]

\[
= \frac{\exp(-[\lambda + \mu])(\lambda + \mu)^t}{t!} \sum_{i=0}^{t} \binom{t}{i} \left( \frac{\lambda}{\lambda + \mu} \right)^i \left( \frac{\mu}{\lambda + \mu} \right)^{t-i}
\]

\[
= \frac{\exp(-[\lambda + \mu])(\lambda + \mu)^t}{t!}
\]
Confidence Bounds for $\rho$

The conditional distribution of $Y$ given $X + Y = t$ is binomial, $n = t$ and $p = \frac{1}{1 + \rho}$

We write $\mathcal{D}(Y \mid X + Y = t) \sim \text{Binomial}(t, p = 1/(1 + \rho))$

$\rho = 1/p - 1$ is strictly decreasing in $p$.

Confidence bounds and intervals translate easily to bounds and intervals for $\rho$.

$$\hat{\rho}_L(\gamma, k, t) = \frac{1}{\hat{\rho}_U(\gamma, k, t)} - 1 = \frac{1}{q\beta\text{eta}(\gamma, k + 1, t - k)} - 1.$$

$$\hat{\rho}_U(\gamma, k, t) = \frac{1}{\hat{\rho}_L(\gamma, k, t)} - 1 = \frac{1}{q\beta\text{eta}(1 - \gamma, k, t - k + 1)} - 1.$$

$$(\hat{\rho}_L([1 + \gamma]/2, k, t), \hat{\rho}_U([1 + \gamma]/2, k, t)) = \left(\frac{1}{\hat{\rho}_U([1 + \gamma]/2, k, t)} - 1, \frac{1}{\hat{\rho}_L([1 + \gamma]/2, k, t)} - 1\right)$$

$$= \left(\frac{1}{q\beta\text{eta}([1 + \gamma]/2, k + 1, t - k)} - 1, \frac{1}{q\beta\text{eta}([1 - \gamma]/2, k, t - k + 1)} - 1\right)$$
Confidence Bounds for $\pi_1 / \pi_2$ (small $\pi_i$)

Assume $X \sim \text{Binomial}(n_1, \pi_1)$, $Y \sim \text{Binomial}(n_2, \pi_2)$ are independent with $\pi_i \approx 0$.

Using Poisson approximations for both binomial distributions

$X \sim \text{Poisson}(\lambda = n_1 \pi_1)$ and $Y \sim \text{Poisson}(\mu = n_2 \pi_2)$

and noting $\rho = (n_1 \pi_1) / (n_2 \pi_2) = \kappa \times n_1 / n_2$ or $\kappa = \pi_1 / \pi_2 = (n_2 / n_1) \times \rho$

confidence bounds and intervals for $\rho$ convert to corresponding ones for $\kappa = \pi_1 / \pi_2$

by multiplying the bounds or interval end points for $\rho$ by $n_2 / n_1$. 
A Fictitious Example

Among Modern Wide Body Airplanes we had 0 accidents (substantial damage, hull loss, or hull loss with fatalities) during $11.128 \times 10^6$ flights. Among Modern Narrow Body Airplanes we had 5 such accidents during $55.6 \times 10^6$ flights.

We have $Y = 5$ and $T = X + Y = t = 0 + 5$, $n_1 = 11.128 \times 10^6$ and $n_2 = 55.6 \times 10^6$.

\[ \Rightarrow \hat{p}_U(.95, 5, 5) = 1 \quad \text{and thus} \quad \hat{k}_L(.95, 5, 5) = \frac{n_2}{n_1} \times \left(\frac{1}{1} - 1\right) = 0 \]

\[ \hat{p}_L(.95, 5, 5) = q_{beta}(.05, 5, 5 - 5 + 1) = (1 - .95)^{1/5} = 0.5492803 \]

\[ \Rightarrow \hat{k}_U(.95, 5, 5) = \frac{n_2}{n_1} \times \left(\frac{1}{0.5492803} - 1\right) = 4.099871 \]

Can view 4.099871 as a 95% upper confidence bound for $\pi_1 / \pi_2$. Since this bound is above 1, one cannot rule out that the rates in the two groups may be the same.

This is not surprising since for a fifth of the exposures one might have expected to see one such accident in the second group. That is not all that different from zero in the realm of counting rare events.
Comparing Hull Loss Rates across Airplane Models

Was the Concorde crash significant compared to experiences of other airplanes?

We made two comparisons, comparing it with the MD11 and the B767.

The MD11 had $X = 5$ hull losses and a rate of 4.59 per $10^6$ departures
the Concorde had $Y = 1$ such loss and a rate of 12.02 per $10^6$ departures.

$\Rightarrow n_1 = 1089325$ and $n_2 = 83195$ departures for MD11 and Concorde, resp.

$\Rightarrow (.04273, 18.06)$ as a 95% confidence interval for $\kappa = \pi_1 / \pi_2$ which contains
$\pi_1 / \pi_2 = 1$ as a possible value.

Thus one cannot conclude that the MD11 and the Concorde had sufficiently
different experiences.
Comparing Hull Loss Rates across Airplane Models

The confidence intervals could be quite conservative in their coverage probabilities based on the fact that only $X + Y = 6$ accidents were involved in this comparison.

Since we are mostly interested in the question $\pi_1 / \pi_2 < 1$ we should focus more on the upper bound for $\pi_1 / \pi_2$.

The 95% upper confidence bound for $\pi_1 / \pi_2$ is 8.896 still $> 1$.

However, here we know that the minimum coverage probability is .95, although its coverage behavior is coarsely fluctuating.

Since the upper bound for $\pi_1 / \pi_2$ is based on the lower bound $\hat{p}_L(\gamma, Y, 6)$ for $p = 1/(1 + \rho) = 1/(1 + n_1 \pi_1 / (n_2 \pi_2))$ we show on the next slide the coverage behavior of this lower bound and indicate by vertical lines positions for various values of $\pi_1 / \pi_2$. 
Coverage Probabilities

Probability of Coverage for $p$ at nominal confidence level = 0.95
sample size $n = 6$

$\pi_1/\pi_2$
- 0.3
- 0.5
- 0.8
- 1.2
The B767 had \( X = 3 \) hull losses and a rate of \( .32 \) per \( 10^6 \) departures.

This translates into \( n_1 = 9375000 \) departures for the B767.

Here our 95\% upper bound for \( \pi_1 / \pi_2 \) is \( .6876 \)

This is clearly below 1 and thus indicates a difference in experience between the B767 and the Concorde, in favor of the B767.
